making big data simple

- Founded in late 2013
- by the creators of Apache Spark
- Original team from UC Berkeley AMPLab
- Raised \$47 Million in 2 rounds
- ~50 employees
- We're hiring! (<http://databricks.workable.com>)
- Level 2/3 support partnerships with
 - Cloudera
 - Hortonworks
 - MapR
 - DataStax

Databricks Cloud:
“A unified platform for building Big Data pipelines – from ETL to Exploration and Dashboards, to Advanced Analytics and Data Products.”

The Databricks team contributed more than **75%** of the code added to Spark in the past year

AGENDA

Before Lunch

- History of Spark
- RDD fundamentals
- Spark Runtime Architecture
Integration with Resource Managers
(Standalone, YARN)
- GUIs
- Lab: DevOps 101

After Lunch

- Memory and Persistence
- Jobs -> Stages -> Tasks
- Broadcast Variables and
Accumulators
- PySpark
- DevOps 102
- Shuffle
- Spark Streaming

Some slides will be skipped

Please keep Q&A low during class

(5pm – 5:30pm for Q&A with instructor)

2 anonymous surveys: Pre and Post class

Lunch: noon – 1pm

2 breaks (before lunch and after lunch)

APPLICATIONS

Spark: Cluster Computing with Working Sets

Matei Zaharia, Mosharaf Chowdhury, Michael J. Franklin, Scott Shenker, Ion Stoica
University of California, Berkeley

Abstract

MapReduce and its variants have been highly successful in implementing large-scale data-intensive applications on commodity clusters. However, most of these systems are built around an acyclic data flow model that is not suitable for other popular applications. This paper focuses on one such class of applications: those that reuse a working set of data across multiple parallel operations. This includes many iterative machine learning algorithms, as well as interactive data analysis tools. We propose a new framework called Spark that supports these applications while retaining the scalability and fault tolerance of MapReduce. To achieve these goals, Spark introduces an abstraction called *resilient distributed datasets* (RDDs). An RDD is a read-only collection of objects partitioned across a set of machines that can be rebuilt if a partition is lost. Spark can outperform Hadoop by 10x in iterative machine learning jobs, and can be used to interactively query a 39 GB dataset with sub-second response time.

1 Introduction

A new model of cluster computing has become widely popular, in which data-parallel computations are executed on clusters of unreliable machines by systems that automatically provide locality-aware scheduling, fault tolerance, and load balancing. MapReduce [11] pioneered this model, while systems like Dryad [17] and MapReduce-Merge [24] generalized the types of data flows supported. These systems achieve their scalability and fault tolerance by providing a programming model where the user creates acyclic data flow graphs to pass input data through a set of operators. This allows the underlying system to manage scheduling and to react to faults without user intervention.

While this data flow programming model is useful for a large class of applications, there are applications that cannot be expressed efficiently as acyclic data flows. In this paper, we focus on one such class of applications: those that reuse a *working set* of data across multiple parallel operations. This includes two use cases where we have seen Hadoop users report that MapReduce is deficient:

- **Iterative jobs:** Many common machine learning algorithms apply a function repeatedly to the same dataset to optimize a parameter (e.g., through gradient descent). While each iteration can be expressed as a

MapReduce/Dryad job, each job must reload the data from disk, incurring a significant performance penalty.

- **Interactive analytics:** Hadoop is often used to run ad-hoc exploratory queries on large datasets, through SQL interfaces such as Pig [21] and Hive [1]. Ideally, a user would be able to load a dataset of interest into memory across a number of machines and query it repeatedly. However, with Hadoop, each query incurs significant latency (tens of seconds) because it runs as a separate MapReduce job and reads data from disk.

This paper presents a new cluster computing framework called Spark, which supports applications with working sets while providing similar scalability and fault tolerance properties to MapReduce.

The main abstraction in Spark is that of a *resilient distributed dataset* (RDD), which represents a read-only collection of objects partitioned across a set of machines that can be rebuilt if a partition is lost. Users can explicitly cache an RDD in memory across machines and reuse it in multiple MapReduce-like parallel operations. RDDs achieve fault tolerance through a notion of *lineage*: if a partition of an RDD is lost, the RDD has enough information about how it was derived from other RDDs to be able to rebuild just that partition. Although RDDs are not a general shared memory abstraction, they represent a sweet-spot between expressivity on the one hand and scalability and reliability on the other hand, and we have found them well-suited for a variety of applications.

Spark is implemented in Scala [5], a statically typed high-level programming language for the Java VM, and exposes a functional programming interface similar to DryadLINQ [25]. In addition, Spark can be used interactively from a modified version of the Scala interpreter, which allows the user to define RDDs, functions, variables and classes and use them in parallel operations on a cluster. We believe that Spark is the first system to allow an efficient, general-purpose programming language to be used interactively to process large datasets on a cluster.

Although our implementation of Spark is still a prototype, early experience with the system is encouraging. We show that Spark can outperform Hadoop by 10x in iterative machine learning workloads and can be used interactively to scan a 39 GB dataset with sub-second latency.

This paper is organized as follows. Section 2 describes

“The main abstraction in Spark is that of a **resilient distributed dataset (RDD)**, which represents a read-only collection of objects partitioned across a set of machines that can be rebuilt if a partition is lost.

Users can explicitly cache an RDD in memory across machines and reuse it in multiple MapReduce-like parallel operations.

RDDs achieve fault tolerance through a notion of **lineage**: if a partition of an RDD is lost, the RDD has enough information about how it was derived from other RDDs to be able to rebuild just that partition.”

Resilient Distributed Datasets: A Fault-Tolerant Abstraction for In-Memory Cluster Computing

Matei Zaharia, Mosharaf Chowdhury, Tathagata Das, Ankur Dave, Justin Ma,
Murphy McCauley, Michael J. Franklin, Scott Shenker, Ion Stoica
University of California, Berkeley

Abstract

We present Resilient Distributed Datasets (RDDs), a distributed memory abstraction that lets programmers perform in-memory computations on large clusters in a fault-tolerant manner. RDDs are motivated by two types of applications that current computing frameworks handle inefficiently: iterative algorithms and interactive data mining tools. In both cases, keeping data in memory can improve performance by an order of magnitude. To achieve fault tolerance efficiently, RDDs provide a restricted form of shared memory, based on coarse-grained transformations rather than fine-grained updates to shared state. However, we show that RDDs are expressive enough to capture a wide class of computations, including recent specialized programming models for iterative jobs, such as Pregel, and new applications that these models do not capture. We have implemented RDDs in a system called Spark, which we evaluate through a variety of user applications and benchmarks.

1 Introduction

Cluster computing frameworks like MapReduce [10] and Dryad [19] have been widely adopted for large-scale data analytics. These systems let users write parallel computations using a set of high-level operators, without having to worry about work distribution and fault tolerance.

Although current frameworks provide numerous abstractions for accessing a cluster's computational resources, they lack abstractions for leveraging distributed memory. This makes them inefficient for an important class of emerging applications: those that *reuse* intermediate results across multiple computations. Data reuse is common in many *iterative* machine learning and graph algorithms, including PageRank, K-means clustering, and logistic regression. Another compelling use case is *interactive* data mining, where a user runs multiple ad-hoc queries on the same subset of the data. Unfortunately, in most current frameworks, the only way to reuse data between computations (*e.g.*, between two MapReduce jobs) is to write it to an external stable storage system, *e.g.*, a distributed file system. This incurs substantial overheads due to data replication, disk I/O, and serializa-

tion, which can dominate application execution times.

Recognizing this problem, researchers have developed specialized frameworks for some applications that require data reuse. For example, Pregel [22] is a system for iterative graph computations that keeps intermediate data in memory, while HaLoop [7] offers an iterative MapReduce interface. However, these frameworks only support specific computation patterns (*e.g.*, looping a series of MapReduce steps), and perform data sharing implicitly for these patterns. They do not provide abstractions for more general reuse, *e.g.*, to let a user load several datasets into memory and run ad-hoc queries across them.

In this paper, we propose a new abstraction called *resilient distributed datasets (RDDs)* that enables efficient data reuse in a broad range of applications. RDDs are fault-tolerant, parallel data structures that let users explicitly persist intermediate results in memory, control their partitioning to optimize data placement, and manipulate them using a rich set of operators.

The main challenge in designing RDDs is defining a programming interface that can provide fault tolerance *efficiently*. Existing abstractions for in-memory storage on clusters, such as distributed shared memory [24], key-value stores [25], databases, and Piccolo [27], offer an interface based on fine-grained updates to mutable state (*e.g.*, cells in a table). With this interface, the only ways to provide fault tolerance are to replicate the data across machines or to log updates across machines. Both approaches are expensive for data-intensive workloads, as they require copying large amounts of data over the cluster network, whose bandwidth is far lower than that of RAM, and they incur substantial storage overhead.

In contrast to these systems, RDDs provide an interface based on *coarse-grained* transformations (*e.g.*, map, filter and join) that apply the same operation to many data items. This allows them to efficiently provide fault tolerance by logging the transformations used to build a dataset (its *lineage*) rather than the actual data.¹ If a partition of an RDD is lost, the RDD has enough information about how it was derived from other RDDs to recompute

¹Checkpointing the data in some RDDs may be useful when a lineage chain grows large, however, and we discuss how to do it in §5.4.

“We present Resilient Distributed Datasets (RDDs), a distributed memory abstraction that lets programmers perform in-memory computations on large clusters in a fault-tolerant manner.

RDDs are motivated by two types of applications that current computing frameworks handle inefficiently: iterative algorithms and interactive data mining tools.

In both cases, keeping data in memory can improve performance by an order of magnitude.”

Spark STREAMING

The screenshot shows a web browser displaying a PDF document. The URL in the address bar is www.cs.berkeley.edu/~matei/papers/2013/sosp_spark_streaming.pdf. The title of the paper is "Discretized Streams: Fault-Tolerant Streaming Computation at Scale". The authors listed are Matei Zaharia, Tathagata Das, Haoyuan Li, Timothy Hunter, Scott Shenker, and Ion Stoica, all from the University of California, Berkeley.

Abstract

Much “big data” applications must act on data in real time. Running these applications at ever-larger scales requires parallel platforms that automatically handle faults and stragglers. Unfortunately, current distributed stream processing models provide fault recovery in an expensive manner, requiring hot replication or long recovery times, and do not handle stragglers. We propose a new processing model, *discretized streams* (D-Streams), that overcomes these challenges. D-Streams enable a *parallel recovery* mechanism that improves efficiency over traditional replication and backup schemes, and tolerates stragglers. We show that they support a rich set of operators while attaining high per-node throughput similar to single-node systems, linear scaling to 100 nodes, sub-second latency, and sub-second fault recovery. Finally, D-Streams can easily be composed with batch and interactive query models like MapReduce, enabling rich applications that combine these modes. We implement D-Streams in a system called Spark Streaming.

1 Introduction

Much of “big data” is received in real time, and is most valuable at its time of arrival. For example, a social network may wish to detect trending conversation topics in

faults and stragglers (slow nodes). Both problems are inevitable in large clusters [12], so streaming applications must recover from them quickly. Fast recovery is even more important in streaming than it was in batch jobs: while a 30 second delay to recover from a fault or straggler is a nuisance in a batch setting, it can mean losing the chance to make a key decision in a streaming setting.

Unfortunately, existing streaming systems have limited fault and straggler tolerance. Most distributed streaming systems, including Storm [37], TimeStream [33], MapReduce Online [11], and streaming databases [5, 9, 10], are based on a *continuous operator* model, in which long-running, stateful operators receive each record, update internal state, and send new records. While this model is quite natural, it makes it difficult to handle faults and stragglers.

Specifically, given the continuous operator model, systems perform recovery through two approaches [20]: *replication*, where there are two copies of each node [5, 34], or *upstream backup*, where nodes buffer sent messages and replay them to a new copy of a failed node [33, 11, 37]. Neither approach is attractive in large clusters: replication costs 2× the hardware, while upstream backup takes a long time to recover, as the whole system must wait for a new node to serially rebuild the failed

GraphX: A Resilient Distributed Graph System on Spark

Reynold S. Xin, Joseph E. Gonzalez, Michael J. Franklin, Ion Stoica

AMPLab, EECS, UC Berkeley
{rxin, jegonzal, franklin, istoica}@cs.berkeley.edu

ABSTRACT

From social networks to targeted advertising, big graphs capture the structure in data and are central to recent advances in machine learning and data mining. Unfortunately, directly applying existing data-parallel tools to graph computation tasks can be cumbersome and inefficient. The need for intuitive, scalable tools for graph computation has led to the development of new *graph-parallel* systems (e.g., Pregel, PowerGraph) which are designed to efficiently execute graph algorithms. Unfortunately, these new graph-parallel systems do not address the challenges of graph construction and transformation which are often just as problematic as the subsequent computation. Furthermore, existing graph-parallel systems provide limited fault-tolerance and support for interactive data mining.

We introduce GraphX, which combines the advantages of both data-parallel and graph-parallel systems by efficiently expressing graph computation within the Spark data-parallel framework. We leverage new ideas in distributed graph representation to efficiently distribute graphs as tabular data-structures. Similarly, we leverage advances in data-flow systems to exploit in-memory computation and fault-tolerance. We provide powerful new operations to simplify graph construction and transformation. Using these primitives we implement the PowerGraph and Pregel abstractions in less than 20 lines of code. Finally, by exploiting the Scala foundation of Spark, we enable users to interactively load, transform, and compute on massive graphs.

1. INTRODUCTION

From social networks to advertising and the web, big graphs can be found in a wide range of important applications. By modeling the

and distributed systems. By abstracting away the challenges of large-scale distributed system design, these frameworks simplify the design, implementation, and application of new sophisticated graph algorithms to large-scale real-world graph problems.

While existing graph-parallel frameworks share many common properties, each presents a slightly different view of graph computation tailored to either the originating domain or a specific family of graph algorithms and applications. Unfortunately, because each framework relies on a separate runtime, it is difficult to compose these abstractions. Furthermore, while these frameworks address the challenges of graph computation, they do not address the challenges of data ETL (preprocessing and construction) or the process of interpreting and applying the results of computation. Finally, few frameworks have built-in support for interactive graph computation.

Alternatively *data-parallel* systems like MapReduce and Spark [12] are designed for scalable data processing and are well suited to the task of graph construction (ETL). By exploiting data-parallelism, these systems are highly scalable and support a range of fault-tolerance strategies. More recent systems like Spark even enable interactive data processing. However, naively expressing graph computation and graph algorithms in these data-parallel abstractions can be challenging and typically leads to complex joins and excessive data movement that does not exploit the graph structure.

To address these challenges we introduce GraphX, a graph computation system which runs in the Spark data-parallel framework. GraphX extends Spark's Resilient Distributed Dataset (RDD) abstraction to introduce the Resilient Distributed Graph (RDG), which associates records with vertices and edges in a graph and provides a collection of expressive computational primitives. Using these

```
graph = Graph(vertices, edges)
messages = spark.textFile("hdfs://...")
graph2 = graph.joinVertices(messages) {
    (id, vertex, msg) => ...
}
```

BlinkDB: Queries with Bounded Errors and Bounded Response Times on Very Large Data

Sameer Agarwal[†], Barzan Mozafari[◦], Aurojit Panda[†], Henry Milner[†], Samuel Madden[◦], Ion Stoica^{*†}

[†]*University of California, Berkeley*

[◦]*Massachusetts Institute of Technology*

^{*}*Conviva Inc.*

{sameerag, apanda, henrym, istoica}@cs.berkeley.edu, {barzan, madden}@csail.mit.edu

Abstract

In this paper, we present BlinkDB, a massively parallel, approximate query engine for running interactive SQL queries on large volumes of data. BlinkDB allows users to trade-off query accuracy for response time, enabling interactive queries over massive data by running queries on data samples and presenting results annotated with meaningful error bars. To achieve this, BlinkDB uses two key ideas: (1) an adaptive optimization framework that builds and maintains a set of multi-dimensional stratified samples from original data over time, and (2) a dynamic sample selection strategy that selects an appropriately sized sample based on a query's accuracy or response time requirements. We evaluate BlinkDB against the well-known TPC-H benchmarks and a real-world analytic workload derived from Conviva Inc., a company that manages video distribution over the Internet. Our experiments on a 100 node cluster show that BlinkDB can answer queries on up to 17 TBs of data in less than 2 seconds (over 200× faster than Hive), within an error of 2-10%.

1. Introduction

Modern data analytics applications involve computing aggregates over a large number of records to *roll-up* web clicks,

cessing of large amounts of data by trading result accuracy for response time and space. These techniques include sampling [10, 14], sketches [12], and on-line aggregation [15]. To illustrate the utility of such techniques, consider the following simple query that computes the average SessionTime over all users originating in New York:

```
SELECT AVG(SessionTime)
FROM Sessions
WHERE City = 'New York'
```

Suppose the Sessions table contains 100 million tuples for New York, and cannot fit in memory. In that case, the above query may take a long time to execute, since disk reads are expensive, and such a query would need multiple disk accesses to stream through all the tuples. Suppose we instead executed the same query on a sample containing only 10,000 New York tuples, such that the entire sample fits in memory. This would be orders of magnitude faster, while still providing an approximate result within a few percent of the actual value, an accuracy good enough for many practical purposes. Using sampling theory we could even provide confidence bounds on the accuracy of the answer [16].

Previously described approximation techniques make different trade-offs between efficiency and the generality of the

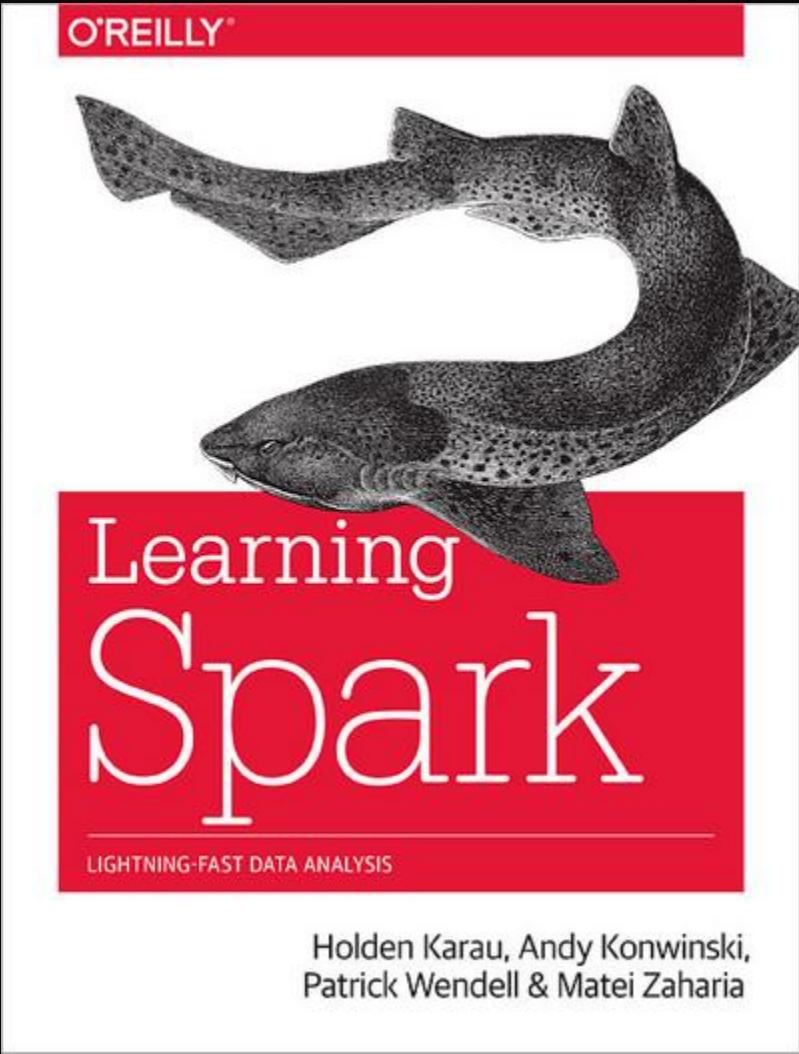

```
SELECT avg(sessionTime)
FROM Table
WHERE city='San Francisco'
WITHIN 2 SECONDS
```

Queries with Time Bounds

```
SELECT avg(sessionTime)

Lab: Intro to Spark 1.1 on DSE 4.6

Lab created on: Sept 2, 2014 (last updated Dec 9, 2014)
(please send edits and corrections to): sameerf@databricks.com

This lab was created with collaboration from engineers at DataStax and Databricks, specifically: Piotr Kołaczkowski (DS), Holden Karau (DB), Pat McDonough (DB), Patrick Wendell (DB) and Matei Zaharia (DB).

Estimated lab completion time: **2.5 hours**

License: 

Objective:

This lab will introduce you to using Apache Spark 1.1 on DataStax Enterprise Edition 4.6.0 in the Amazon cloud. The lab assumes that the audience is a beginner to both Cassandra and Spark. So the document walks the reader through installing DSE, learning Cassandra and then learning Spark. The ultimate goal here is to introduce students to Cassandra + Spark in a devops manner: looking at config files, writing some simple CQL or Spark code, breaking things and troubleshooting issues, exploring the Spark source code, etc. Although the ideal way to use this lab is actually type + run the commands in a parallel environment, the lab can still be used for purely reading. All the output of the commands are pasted in this lab, so you can get a very clear idea of what would happen if you had actually run the command.

The following high level steps are part of this lab:

- Connect via SSH to your EC2 instance
- Create a new keyspace and table in C* and add data to it
- Start the scala based Spark shell
- Import the fresh data into a Spark RDD

<http://tinyurl.com/dsesparklab>

- 102 pages
- DevOps style
- For complete beginners
- Includes:
 - Spark Streaming
 - Dangers of
GroupByKey vs.
ReduceByKey

Labs: Intro to Hadoop Ecosystem on CDH 5.2

Labs: Intro to HDFS/YARN & Apache Spark on CDH 5.2

Lab created on: Dec, 2014

(please send edits and corrections to): sameerf@databricks.com

Estimated lab completion time: **2 hours** (spread throughout the day)

License:

Objective:

This lab will introduce you to using 3 Hadoop ecosystem components in Cloudera's distribution: HDFS, Spark 1.1.0 and YARN. The lab will first walk you through the Cloudera Manager installation on a VM in AWS, followed by a CDH 5.2 binaries deployment on the same node. Then the lab will introduce students to Hadoop in a DevOps manner: experimenting with the distributed file system, looking at the XML config files, running a batch analytics workload with Spark from disk and from memory, writing some simple scala Spark code, running SQL commands with Spark SQL, breaking things and troubleshooting issues, etc.

The following high level steps are in the initial part of this lab:

- Connect via SSH to your Amazon instance
- Install Cloudera Manager and CDH 5.2
- Create a new folder in HDFS and add data files to it
- Start the scala based Spark shell
- Import the fresh data into Spark a RDD

# Parallelize in Python
wordsRDD = sc.parallelize(["fish", "cats", "dogs"])
```

```
// Parallelize in Scala
val wordsRDD= sc.parallelize(List("fish", "cats", "dogs"))
```

```
// Parallelize in Java
JavaRDD<String> wordsRDD = sc.parallelize(Arrays.asList("fish", "cats", "dogs"));
```

- Take an existing in-memory collection and pass it to SparkContext's parallelize method
- Not generally used outside of prototyping and testing since it requires entire dataset in memory on one machine

READ FROM TEXT FILE

```
# Read a local txt file in Python  
linesRDD = sc.textFile("/path/to/README.md")
```

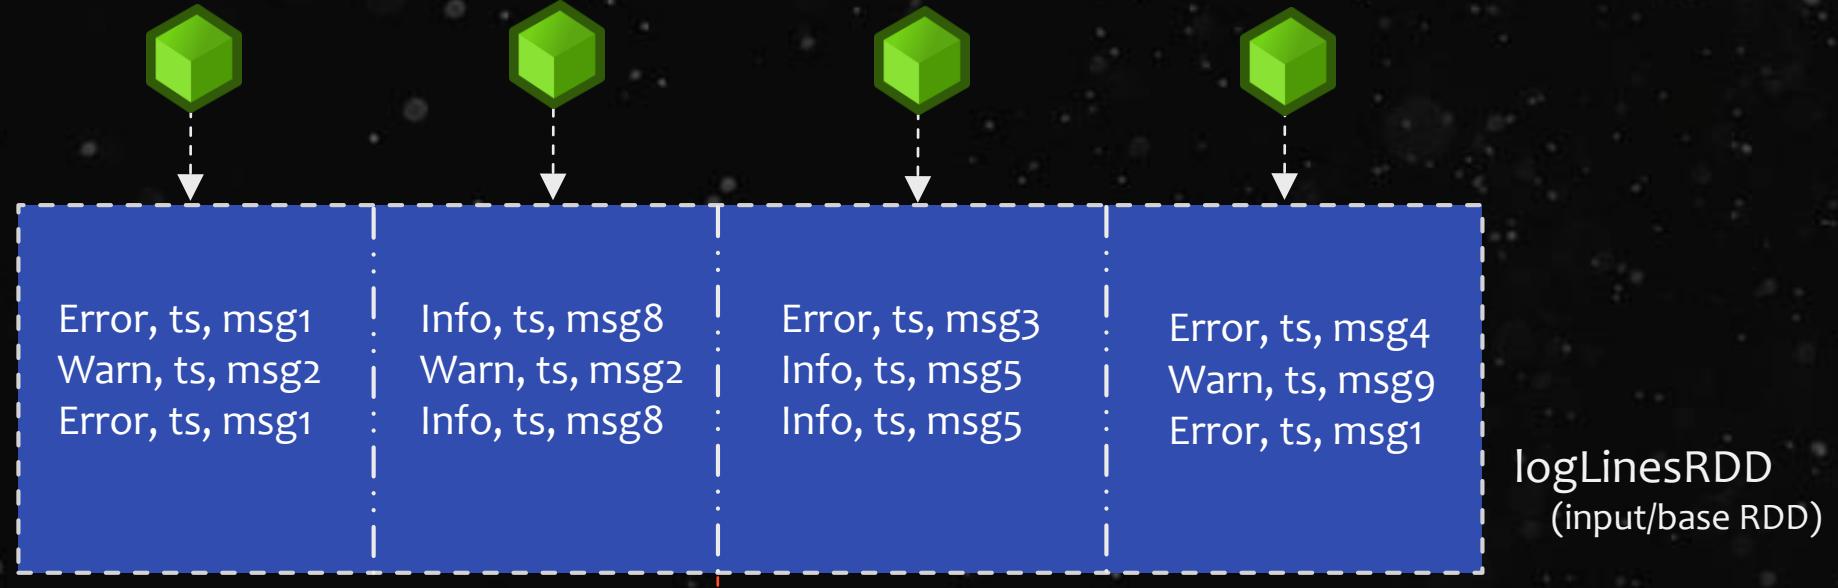

- There are other methods to read data from HDFS, C*, S3, HBase, etc.

```
// Read a local txt file in Scala  
val linesRDD = sc.textFile("/path/to/README.md")
```

```
// Read a local txt file in Java  
JavaRDD<String> lines = sc.textFile("/path/to/README.md");
```

errorsRDD
(output RDD)

Execute DAG!

.collect()

```

- rdd: org.apache.spark.rdd.RDD[String] = MapPartitionsRDD[0] at parallelize at repl:1
- scala> rdd.collect()
- res1: List[String] = ["insecure", "unsafeletinit"]

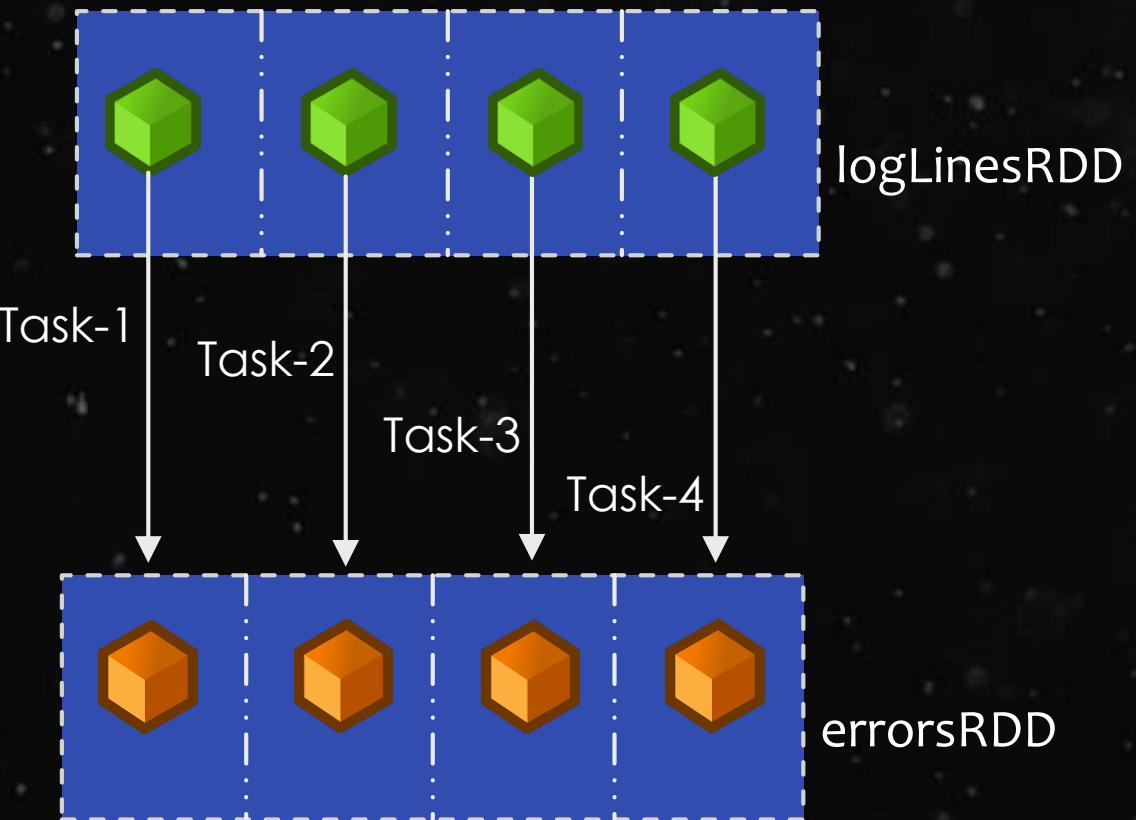

RDD GRAPH

Dataset-level view:

Partition-level view:

LIFECYCLE OF A SPARK PROGRAM

- 1) Create some input RDDs from external data or parallelize a collection in your driver program.
- 2) Lazily transform them to define new RDDs using transformations like `filter()` or `map()`
- 3) Ask Spark to `cache()` any intermediate RDDs that will need to be reused.
- 4) Launch actions such as `count()` and `collect()` to kick off a parallel computation, which is then optimized and executed by Spark.

TRANSFORMATIONS (lazy)

<code>map()</code>	<code>intersection()</code>	<code>cartesian()</code>
<code>flatMap()</code>	<code>distinct()</code>	<code>pipe()</code>
<code>filter()</code>	<code>groupByKey()</code>	<code>coalesce()</code>
<code>mapPartitions()</code>	<code>reduceByKey()</code>	<code>repartition()</code>
<code>mapPartitionsWithIndex()</code>	<code>sortByKey()</code>	<code>partitionBy()</code>
<code>sample()</code>	<code>join()</code>	...
<code>union()</code>	<code>cogroup()</code>	...

- Most transformations are element-wise (they work on one element at a time), but this is not true for all transformations

ACTIONS

reduce()	takeOrdered()
collect()	saveAsTextFile()
count()	saveAsSequenceFile()
first()	saveAsObjectFile()
take()	countByKey()
takeSample()	foreach()
saveToCassandra()	...

TYPES OF RDDS

- HadoopRDD
- FilteredRDD
- MappedRDD
- PairRDD
- ShuffledRDD
- UnionRDD
- PythonRDD
- DoubleRDD
- JdbcRDD
- JsonRDD
- SchemaRDD
- VertexRDD
- EdgeRDD
- CassandraRDD (*DataStax*)
- GeoRDD (*ESRI*)
- EsSpark (*ElasticSearch*)

RDD INTERFACE

- * 1) Set of partitions (“splits”)
- * 2) List of dependencies on parent RDDs
- * 3) Function to compute a partition given parents
- * 4) Optional preferred locations
- * 5) Optional partitioning info for k/v RDDs (Partitioner)

This captures all current Spark operations!

EXAMPLE: HADOOPRDD

- * Partitions = one per HDFS block
 - * Dependencies = none
 - * Compute (partition) = read corresponding block
-
- * preferredLocations (part) = HDFS block location
 - * Partitioner = none

EXAMPLE: FILTEREDRDD

- * Partitions = same as parent RDD
 - * Dependencies = “one-to-one” on parent
 - * Compute (partition) = compute parent and filter it
-
- * preferredLocations (part) = none (ask parent)
 - * Partitioner = none

EXAMPLE: JOINEDRDD

- * Partitions = One per reduce task
 - * Dependencies = “shuffle” on each parent
 - * Compute (partition) = read and join shuffled data
-
- * preferredLocations (part) = none
 - * Partitioner = HashPartitioner(numTasks)

READING DATA USING THE C* CONNECTOR

```
val cassandraRDD = sc  
          .cassandraTable("ks", "mytable")  
          .select("col-1", "col-3")  
          .where("col-5 = ?", "blue")  
Server side column & row selection {
```

Keyspace Table
↓ ↓

INPUT SPLIT SIZE

(for dealing with wide rows)

- Start the Spark shell by passing in a custom `cassandra.input.split.size`:

```
ubuntu@ip-10-0-53-24:~$ dse spark -Dspark.cassandra.input.split.size=2000
Welcome to
```

```
   _\_\_/\_ _\_\_/\_`/\_/\_/\_
 /_\_/\_._\_/\_,/_/\_/\_/\_\
 /_/_/
```

```
Using Scala version 2.10.3 (Java HotSpot(TM) 64-Bit Server VM, Java
1.7.0_51)
```

```
Type in expressions to have them evaluated.
```

```
Type :help for more information.
```

```
Creating SparkContext...
```

```
Created spark context..
```

```
Spark context available as sc.
```

```
Type in expressions to have them evaluated.
```

```
Type :help for more information.
```

```
scala>
```

The `cassandra.input.split.size` parameter defaults to 100,000. This is the approximate number of physical rows in a single Spark partition. If you have really wide rows (thousands of columns), you may need to lower this value. The higher the value, the fewer Spark tasks are created. Increasing the value too much may limit the parallelism level."

- Open Source
- Implemented mostly in Scala
- Scala + Java APIs
- Does automatic type conversions

Spark Cassandra Connector build passing

Lightning-fast cluster computing with Spark and Cassandra

This library lets you expose Cassandra tables as Spark RDDs, write Spark RDDs to Cassandra tables, and execute arbitrary CQL queries in your Spark applications.

Features

- Compatible with Apache Cassandra version 2.0 or higher and DataStax Enterprise 4.5
- Compatible with Apache Spark 1.0 and 1.1
- Exposes Cassandra tables as Spark RDDs
- Maps table rows to CassandraRow objects or tuples
- Offers customizable object mapper for mapping rows to objects of user-defined classes
- Saves RDDs back to Cassandra by implicit `saveToCassandra` call
- Converts data types between Cassandra and Scala
- Supports all Cassandra data types including collections
- Filters rows on the server side via the CQL `WHERE` clause
- Allows for execution of arbitrary CQL statements
- Plays nice with Cassandra Virtual Nodes

“Simple things
should be simple,
complex things
should be possible”

- Alan Kay

PLUGGABLE RESOURCE MANAGEMENT

	Spark Central Master	Who starts Executors?	Tasks run in
Local	[none]	Human being	Executor
Standalone	Standalone Master	Worker JVM	Executor
YARN	YARN App Master	Node Manager	Executor
Mesos	Mesos Master	Mesos Slave	Executor

DEPLOYING AN APP TO THE CLUSTER

`spark-submit` provides a uniform interface for submitting jobs across all cluster managers

```
bin/spark-submit --master spark://host:7077  
--executor-memory 10g  
my_script.py
```

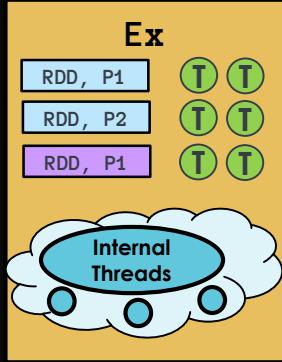

Table 7-2. Possible values for the `--master` flag in `spark-submit`

Value	Explanation
spark://host:port	Connect to a Spark Standalone master at the specified port. By default Spark Standalone master's listen on port 7077 for submitted jobs.
mesos://host:port	Connect to a Mesos cluster master at the specified port. By default Mesos masters listen on port 5050 for submitted jobs.
yarn	Indicates submission to YARN cluster. When running on YARN you'll need to export HADOOP_CONF_DIR to point the location of your Hadoop configuration directory.
local	Run in local mode with a single core.
local[N]	Run in local mode with N cores.
local[*]	Run in local mode and use as many cores as the machine has.

MEMORY AND PERSISTENCE

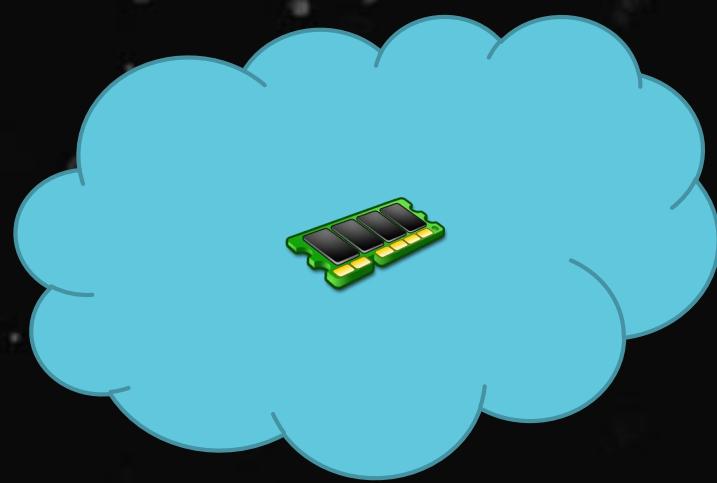

Recommended to use at most only 75% of a machine's memory for Spark

Minimum Executor heap size should be 8 GB

Max Executor heap size depends... maybe 40 GB (watch GC)

Memory usage is greatly affected by storage level and serialization format

Vs.

`RDD.cache() == RDD.persist(MEMORY_ONLY)`

most CPU-efficient option

Stages

Storage

Environment

Executors

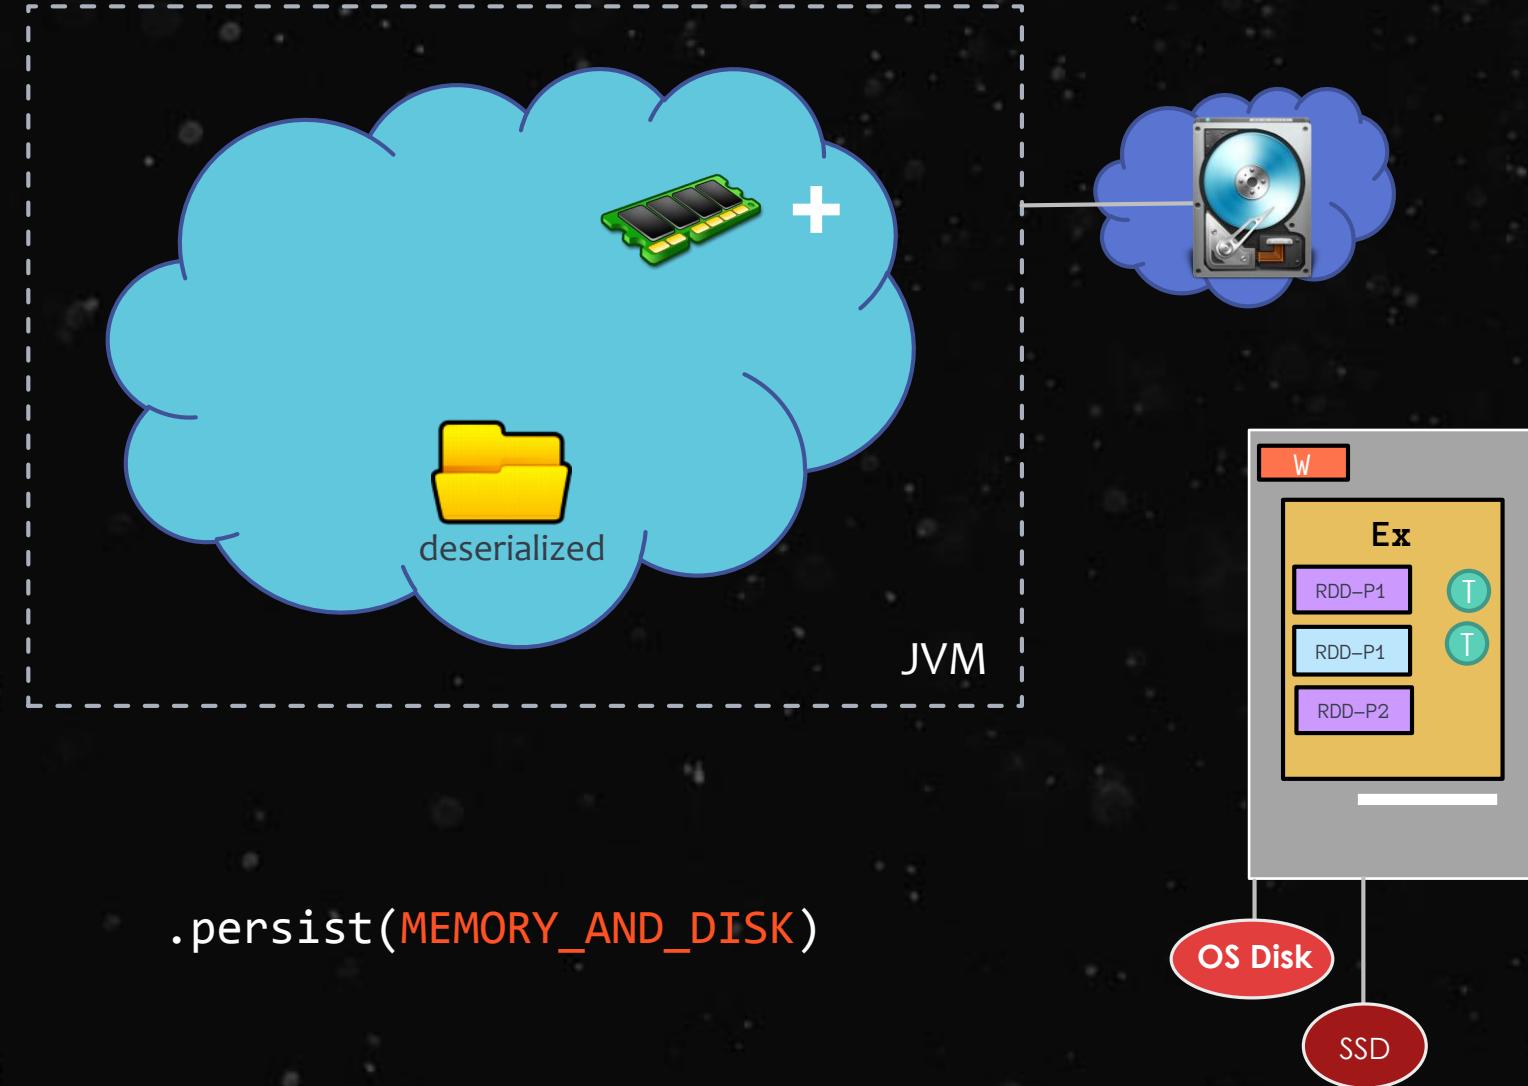

Spark shell application UI

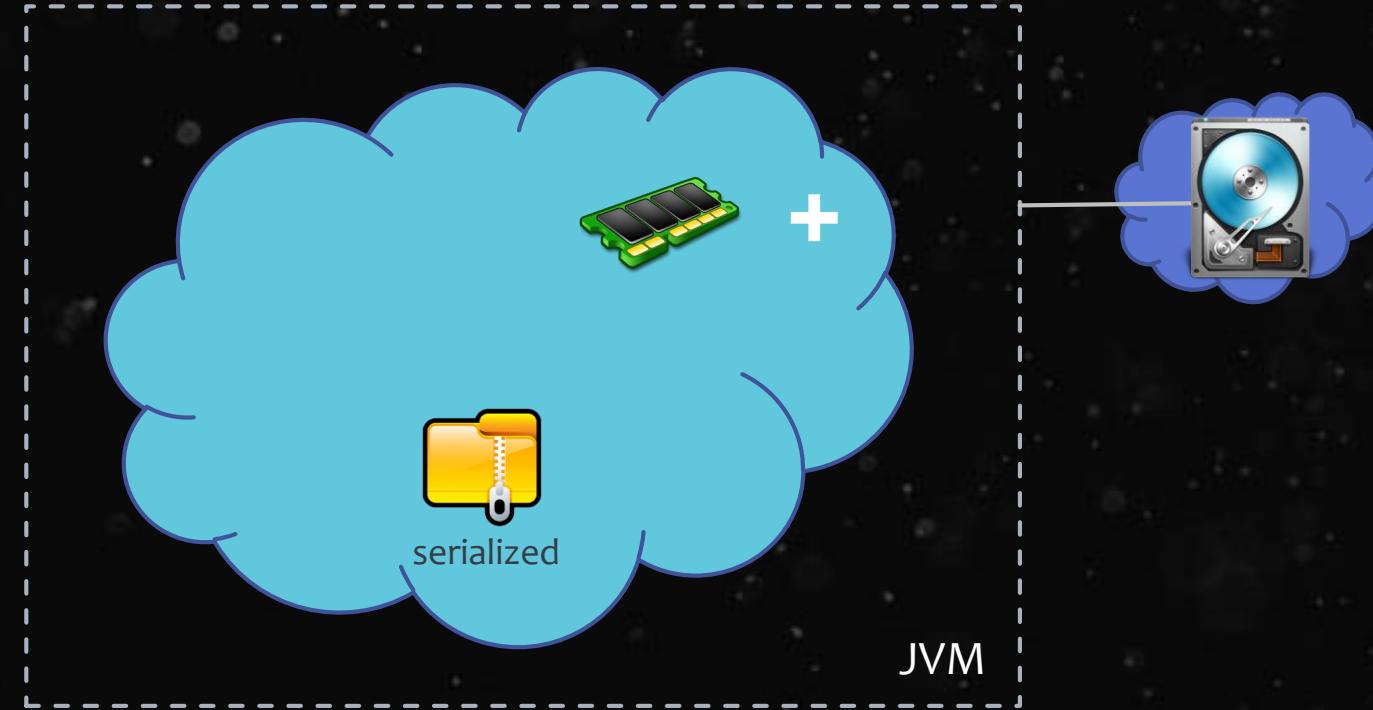

Storage

RDD Name	Storage Level	Cached Partitions	Fraction Cached	Size in Memory	Size on Disk
0	Memory Deserialized 1x Replicated	2	100%	55.6 KB	0.0 B

```
RDD.persist(MEMORY_ONLY_SER)
```

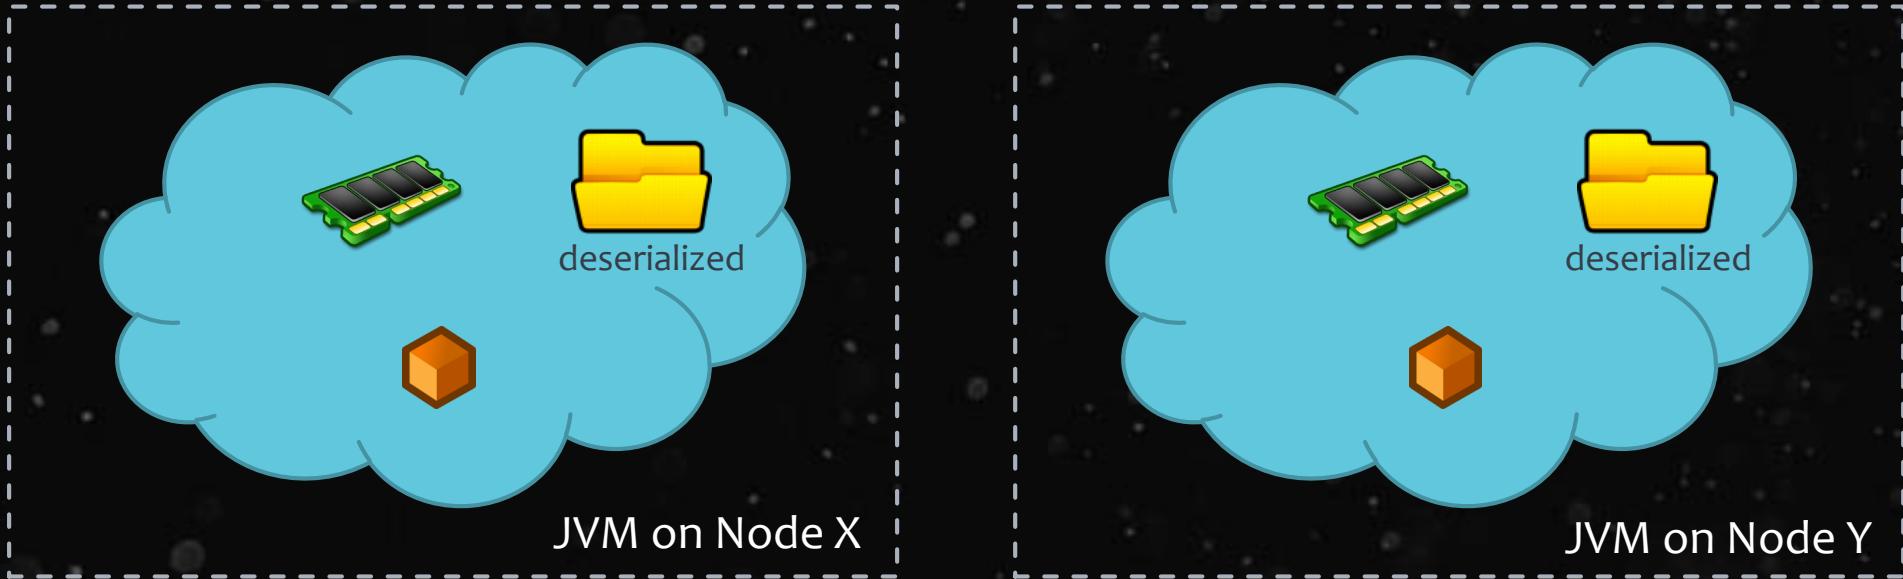

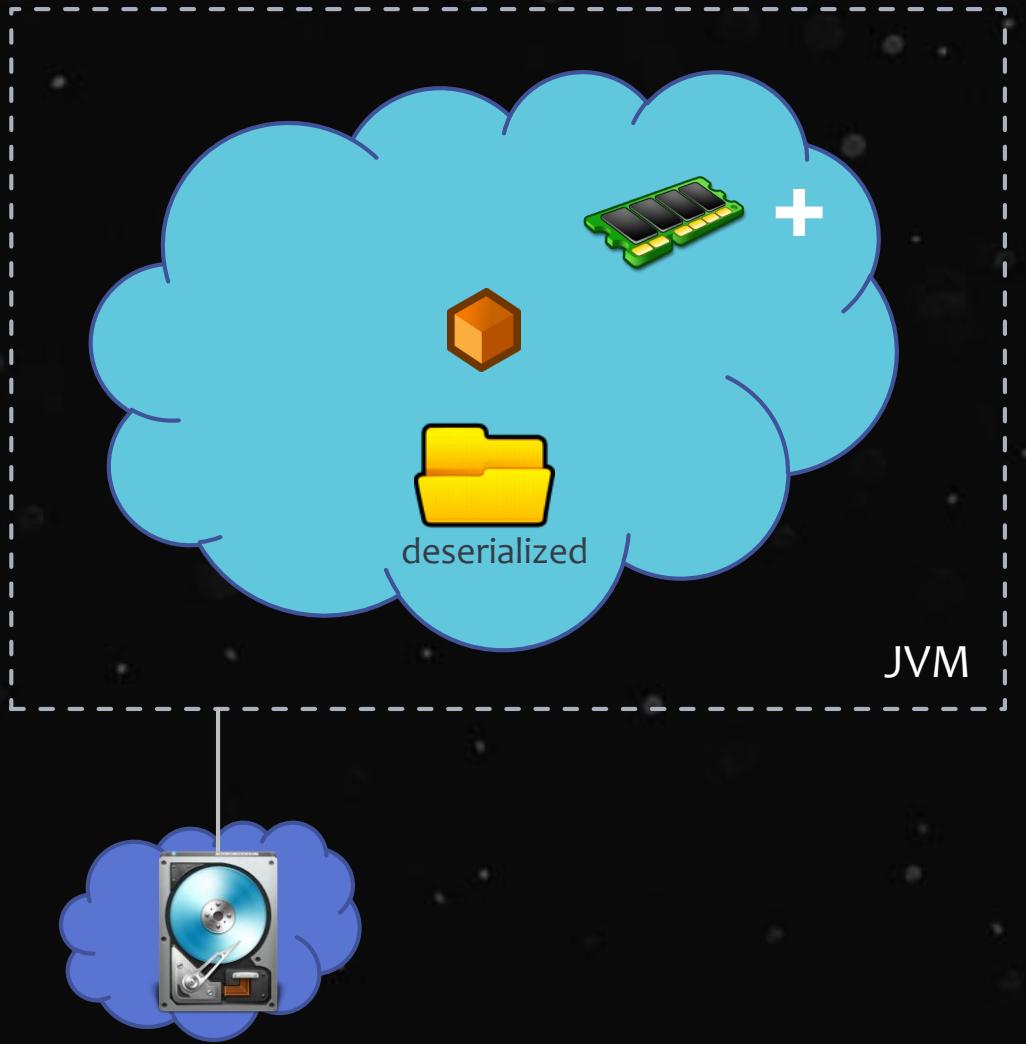

`.persist(MEMORY_AND_DISK_SER)`

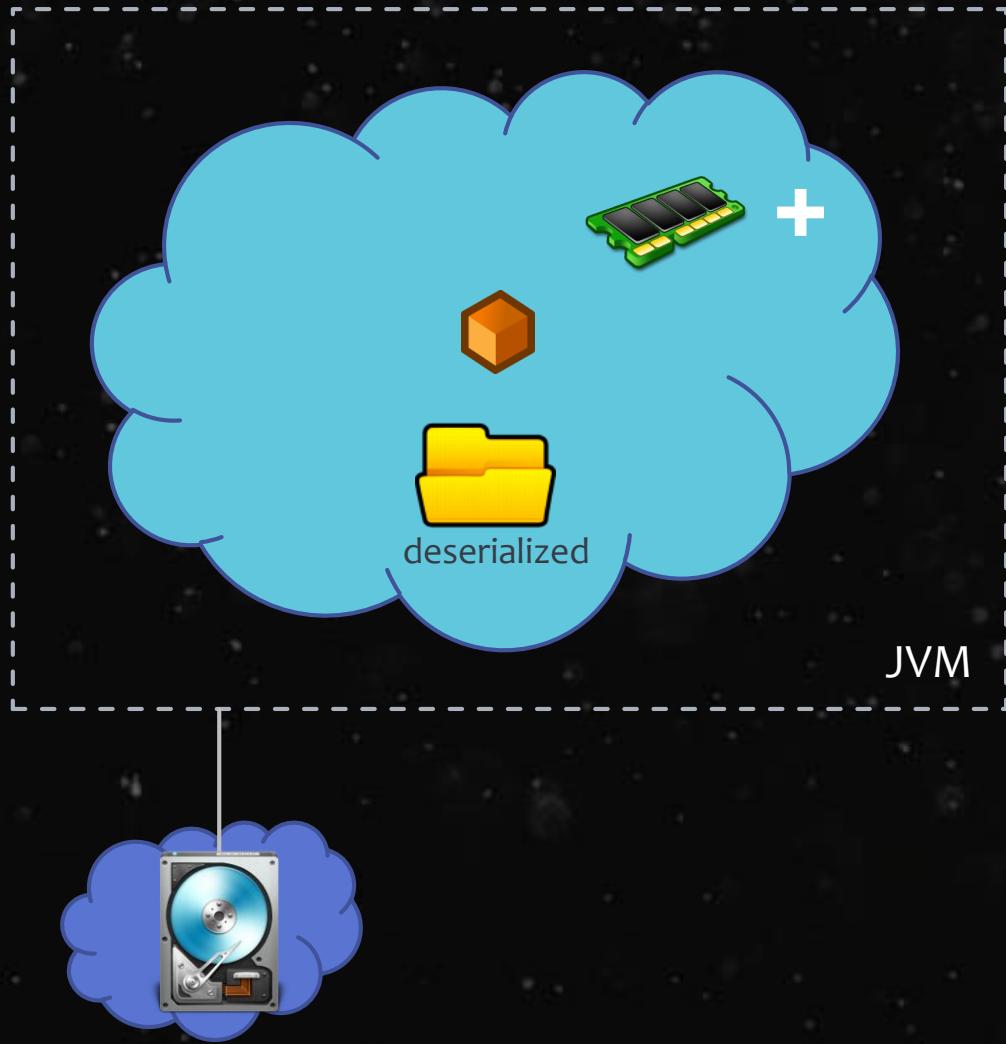

.persist(DISK_ONLY)

`RDD.persist(MEMORY_ONLY_2)`

```
.persist(MEMORY_AND_DISK_2)
```

.persist(OFF_HEAP)

.unpersist()

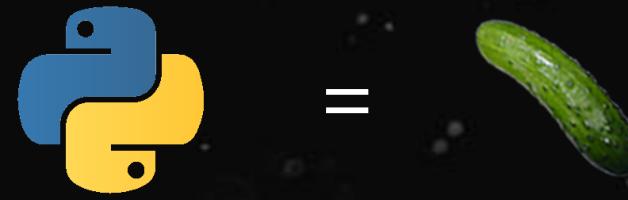

- If RDD fits in memory, choose `MEMORY_ONLY`
- If not, use `MEMORY_ONLY_SER` w/ fast serialization library
- Don't spill to disk unless functions that computed the datasets are very expensive or they filter a large amount of data.
(recomputing may be as fast as reading from disk)
- Use replicated storage levels sparingly and only if you want fast fault recovery (maybe to serve requests from a web app)

Remember!

Intermediate data is automatically persisted during shuffle operations

PySpark: stored objects will always be serialized with Pickle library, so it does not matter whether you choose a serialized level.

Default Memory Allocation in Executor JVM

FIX THIS

MEMORY

Spark uses memory for:

RDD Storage: when you call `.persist()` or `.cache()`. Spark will limit the amount of memory used when caching to a certain fraction of the JVM's overall heap, set by `spark.storage.memoryFraction`

Shuffle and aggregation buffers: When performing shuffle operations, Spark will create intermediate buffers for storing shuffle output data. These buffers are used to store intermediate results of aggregations in addition to buffering data that is going to be directly output as part of the shuffle.

User code: Spark executes arbitrary user code, so user functions can themselves require substantial memory. For instance, if a user application allocates large arrays or other objects, these will contribute to overall memory usage. User code has access to everything “left” in the JVM heap after the space for RDD storage and shuffle storage are allocated.

DETERMINING MEMORY CONSUMPTION

1. Create an RDD
2. Put it into cache
3. Look at SparkContext logs
on the driver program or
Spark UI

logs will tell you how much memory each partition is consuming, which you can aggregate to get the total size of the RDD

```
INFO BlockManagerMasterActor: Added rdd_0_1 in memory on mbk.local:50311 (size: 717.5 KB, free: 332.3 MB)
```

DATA SERIALIZATION

SERIALIZATION

Serialization is used when:

Transferring data over the network

Spilling data to disk

Caching to memory serialized

Broadcasting variables

Java serialization

vs.

Kryo serialization

- Uses Java's `ObjectOutputStream` framework
- Works with any class you create that implements `java.io.Serializable`
- You can control the performance of serialization more closely by extending `java.io.Externalizable`
- Flexible, but quite slow
- Leads to large serialized formats for many classes

- Recommended serialization for production apps
- Use Kryo version 2 for speedy serialization (10x) and more compactness
- Does not support all `Serializable` types
- Requires you to *register* the classes you'll use in advance
- If set, will be used for serializing shuffle data between nodes and also serializing RDDs to disk

```
conf.set("spark.serializer", "org.apache.spark.serializer.KryoSerializer")
```

To register your own custom classes with Kryo, use the `registerKryoClasses` method:

```
val conf = new SparkConf().setMaster(...).setAppName(...)  
conf.registerKryoClasses(Seq(classOf[MyClass1], classOf[MyClass2]))  
val sc = new SparkContext(conf)
```

- If your objects are large, you may need to increase `spark.kryoserializer.buffer.mb` config property
- The default is 2, but this value needs to be large enough to hold the *largest* object you will serialize.

TUNING FOR *Spark*

High churn

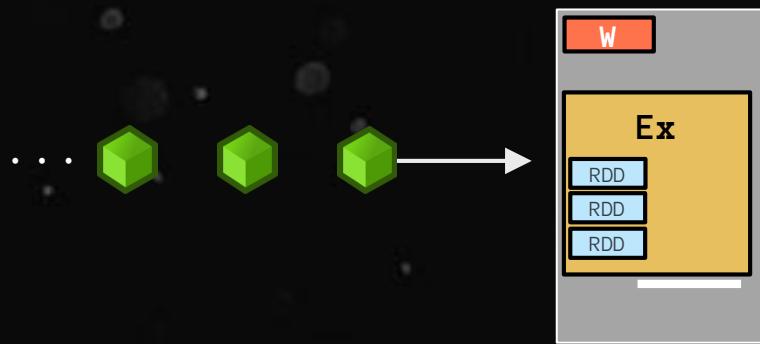

Low churn

TUNING FOR Spark

Cost of GC is proportional to the # of Java objects

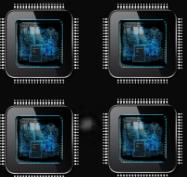

(so use an array of Ints instead of a
LinkedList)

High churn

To measure GC impact:

```
-verbose:gc -XX:+PrintGCDetails -XX:+PrintGCTimeStamps
```

TUNING

Parallel GC

- XX:+UseParallelGC
- XX:ParallelGCThreads=<#>
- Uses multiple threads to do young gen GC
- Will default to Serial on single core machines
- Aka “throughput collector”
- Good for when a lot of work is needed and long pauses are acceptable
- Use cases: batch processing

Parallel Old GC

- XX:+UseParallelOldGC
- Uses multiple threads to do both young gen and old gen GC
- Also a multithreading compacting collector
- HotSpot does compaction only in old gen

CMS GC

- XX:+UseConcMarkSweepGC
- XX:ParallelCMSThreads=<#>
- Concurrent Mark Sweep aka “Concurrent low pause collector”
- Tries to minimize pauses due to GC by doing most of the work concurrently with application threads
- Uses same algorithm on young gen as parallel collector
- Use cases:

G1 GC

- XX:+UseG1GC
- Garbage First is available starting Java 7
- Designed to be long term replacement for CMS
- Is a parallel, concurrent and incrementally compacting low-pause GC

LINEAGE

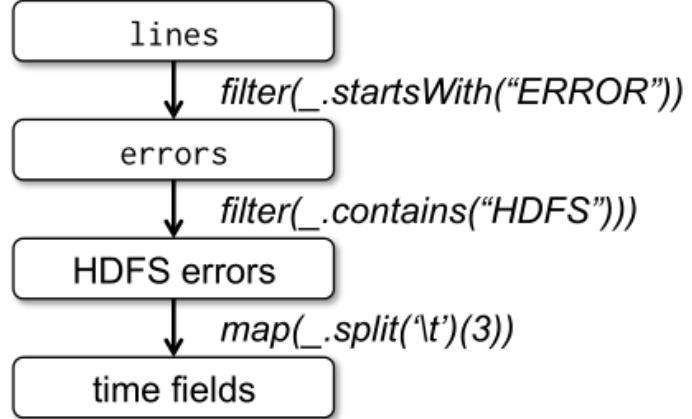

Figure 1: Lineage graph for the third query in our example.
Boxes represent RDDs and arrows represent transformations.

```
lines = spark.textFile("hdfs://...")  
errors = lines.filter(_.startsWith("ERROR"))  
errors.persist()
```

LINEAGE

“One of the challenges in providing RDDs as an abstraction is choosing a representation for them that can track lineage across a wide range of transformations.”

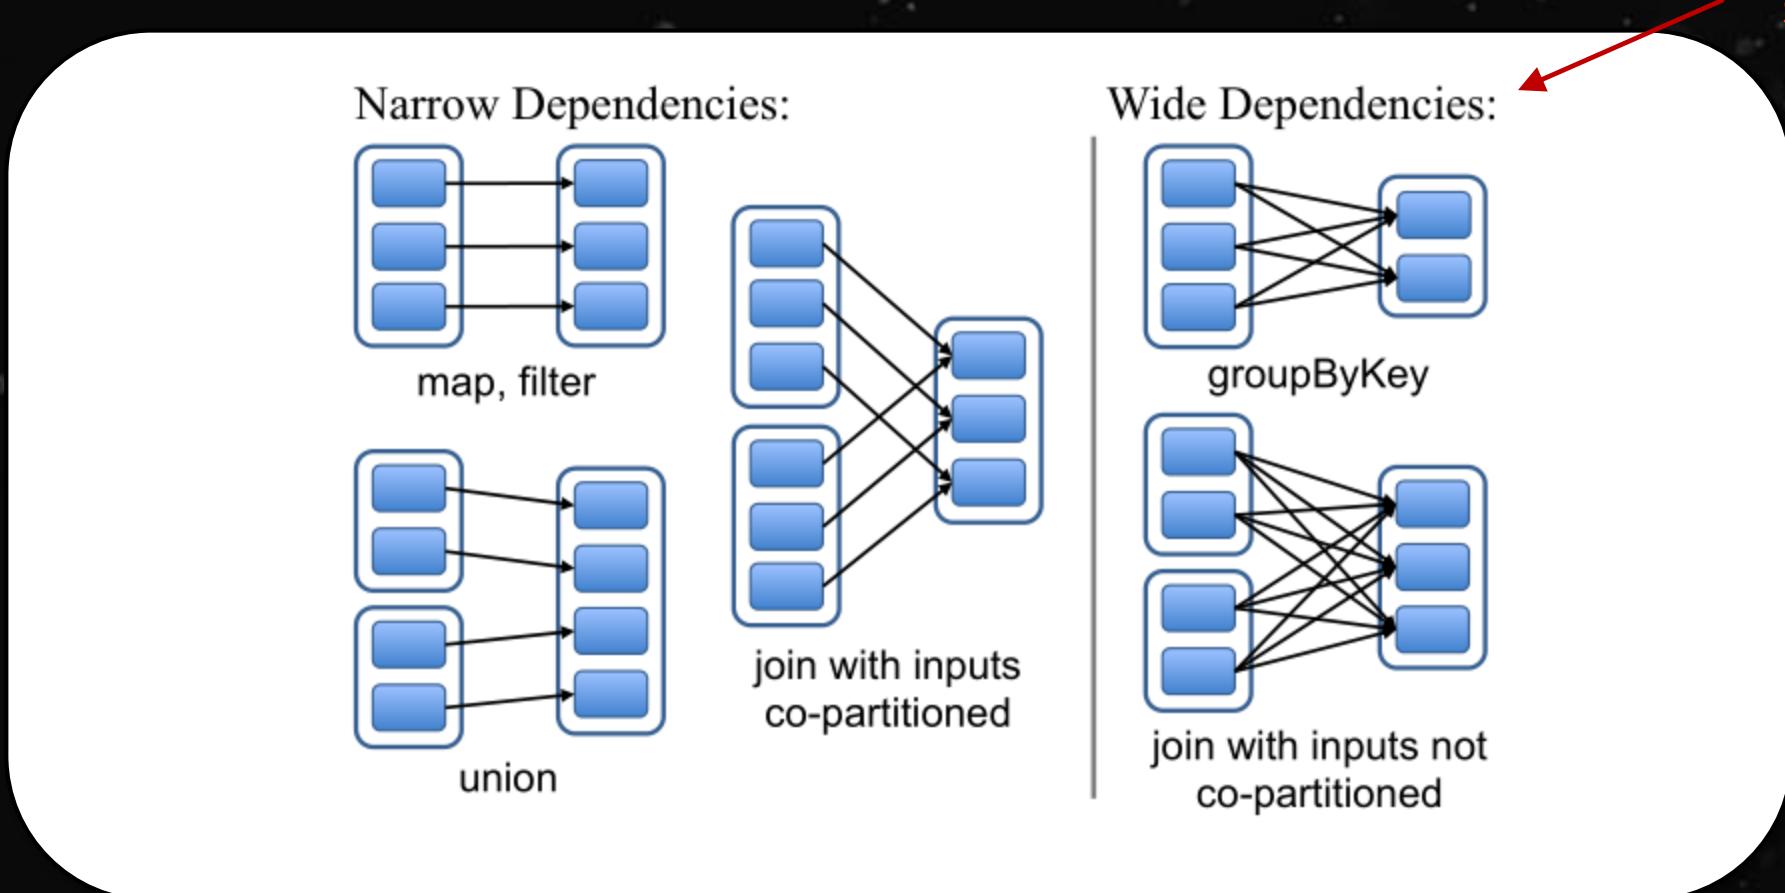

“The most interesting question in designing this interface is how to represent dependencies between RDDs.”

“We found it both sufficient and useful to classify dependencies into two types:

- narrow dependencies, where each partition of the parent RDD is used by at most one partition of the child RDD
- wide dependencies, where multiple child partitions may depend on it.”

LINEAGE DEPENDENCIES

Examples of narrow and wide dependencies.

Each box is an RDD, with partitions shown as shaded rectangles.

STAGES

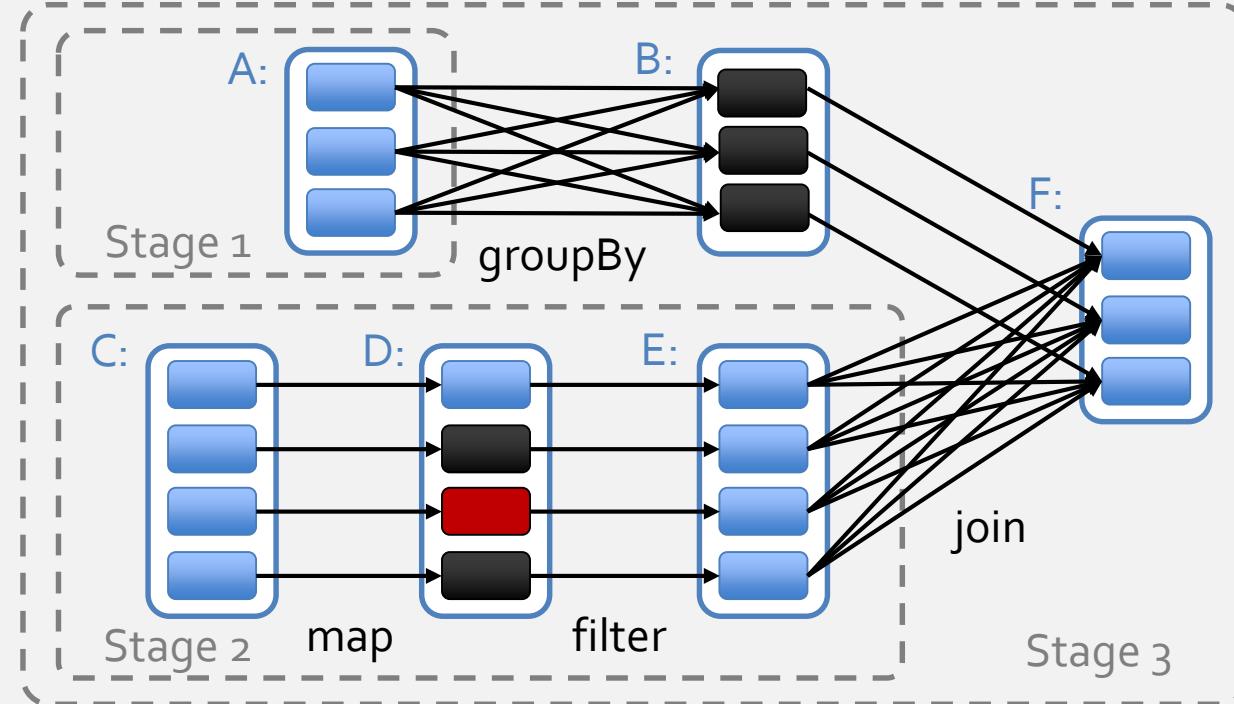

= RDD

= cached partition

= lost partition

LINEAGE

Dependencies: Narrow vs Wide

"This distinction is useful for two reasons:

1) Narrow dependencies allow for pipelined execution on one cluster node, which can compute all the parent partitions. For example, one can apply a map followed by a filter on an element-by-element basis.

In contrast, wide dependencies require data from all parent partitions to be available and to be shuffled across the nodes using a MapReduce-like operation.

2) Recovery after a node failure is more efficient with a narrow dependency, as only the lost parent partitions need to be recomputed, and they can be recomputed in parallel on different nodes. In contrast, in a lineage graph with wide dependencies, a single failed node might cause the loss of some partition from all the ancestors of an RDD, requiring a complete re-execution."

To display the lineage of an RDD, Spark provides a `toDebugString` method:

```
ec2-user@ip-10-0-12-60:~ [ec2-user@ip-10-0-12-60 ~]$ dse spark

```

How do you know if a shuffle will be called on a Transformation?

- repartition , join, cogroup, and any of the *By or *ByKey transformations can result in shuffles
- If you declare a numPartitions parameter, it'll probably shuffle
- If a transformation constructs a shuffledRDD, it'll probably shuffle
- combineByKey calls a shuffle (so do other transformations like groupByKey, which actually end up calling combineByKey)

Note that repartition just calls coalesce w/ True:

RDD.scala

```
def repartition(numPartitions: Int)(implicit  
ord: Ordering[T] = null): RDD[T] = {  
    coalesce(numPartitions, shuffle = true)  
}
```

How do you know if a shuffle will be called on a Transformation?

Transformations that use “numPartitions” like distinct will probably shuffle:

```
def distinct(numPartitions: Int)(implicit ord: Ordering[T] =  
null): RDD[T] =  
    map(x => (x, null)).reduceByKey((x, y) => x,  
    numPartitions).map(_._1)
```

PERSERVES PARTITIONING

- An extra parameter you can pass a k/v transformation to let Spark know that you will not be messing with the keys at all
- All operations that shuffle data over network will benefit from partitioning
- Operations that benefit from partitioning:
`cogroup, groupWith, join, leftOuterJoin, rightOuterJoin, groupByKey, reduceByKey, combineByKey, lookup, . . .`

<https://github.com/apache/spark/blob/master/core/src/main/scala/org/apache/spark/rdd/RDD.scala#L302>

```
299  /**
300   * Return a new RDD containing only the elements that satisfy a predicate.
301   */
302  def filter(f: T => Boolean): RDD[T] = {
303    val cleanF = sc.clean(f)
304    new MapPartitionsRDD[T, T](
305      this,
306      (context, pid, iter) => iter.filter(cleanF),
307      preservesPartitioning = true)
308  }
```

How-to: Tune Your Apache Spark Jobs (Part 1)

by Sandy Ryza | March 09, 2015 |  no comments

Learn techniques for tuning your Apache Spark jobs for optimal efficiency.

(Editor's note: Sandy presents on "[Estimating Financial Risk with Spark](#)" at Spark Summit East on March 18.)

When you write Apache Spark code and page through the public APIs, you come across words like *transformation*, *action*, and *RDD*. Understanding Spark at this level is vital for writing Spark programs. Similarly, when things start to fail, or when you venture into the web UI to try to understand why your application is taking so long, you're confronted with a new vocabulary of words like *job*, *stage*, and *task*. Understanding Spark at this level is vital for writing *good* Spark programs, and of course by *good*, I mean *fast*. To write a Spark program that will execute efficiently, it is very, very helpful to understand Spark's underlying execution model.

In this post, you'll learn the basics of how Spark programs are actually executed on a cluster. Then, you'll get some practical recommendations about what Spark's execution model means for writing efficient programs.

How Spark Executes Your Program

A Spark application consists of a single *driver* process and a set of *executor* processes scattered across nodes on the cluster.

The driver is the process that is in charge of the high-level control flow of work that needs to be done. The executor processes are responsible for executing this work, in the form of *tasks*, as well as for storing any data that the user chooses to cache. Both the driver and the executors typically stick around for the entire time the application is running, although **dynamic resource allocation** changes that for the latter. A single executor has a number of slots for running tasks, and will run many concurrently throughout its lifetime. Deploying these processes on the cluster is up to the cluster manager in use (YARN, Mesos, or Spark Standalone), but the driver and executor themselves exist in every Spark application.

```

$x = 5$

USE CASES:

- Broadcast variables – Send a large read-only lookup table to all the nodes, or send a large feature vector in a ML algorithm to all nodes

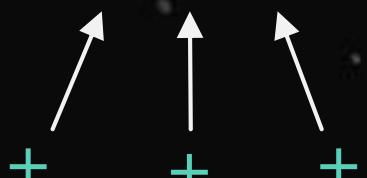

- Accumulators – count events that occur during job execution for debugging purposes. Example: How many lines of the input file were blank? Or how many corrupt records were in the input dataset?

Spark supports 2 types of shared variables:

- Broadcast variables – allows your program to efficiently send a large, read-only value to all the worker nodes for use in one or more Spark operations. Like sending a large, read-only lookup table to all the nodes.
- Accumulators – allows you to aggregate values from worker nodes back to the driver program. Can be used to count the # of errors seen in an RDD of lines spread across 100s of nodes. Only the driver can access the value of an accumulator, tasks cannot. For tasks, accumulators are write-only.

BROADCAST VARIABLES

Broadcast variables let programmer keep a read-only variable cached on each machine rather than shipping a copy of it with tasks

For example, to give every node a copy of a large input dataset efficiently

Spark also attempts to distribute broadcast variables using efficient broadcast algorithms to reduce communication cost

BROADCAST VARIABLES

Scala:

```
val broadcastVar = sc.broadcast(Array(1, 2, 3))
broadcastVar.value
```

Python:

```
broadcastVar = sc.broadcast(list(range(1, 4)))
broadcastVar.value
```

The screenshot shows a web browser window with a dark theme. The address bar displays the URL www.mosharaf.com/blog/2014/09/22/orchestra-is-the-default-broadcast-mechanism-in-apache-spark. The page header includes the site name "Mosharaf Chowdhury" and a navigation menu with links for HOME, PUBLICATIONS, TALKS, TEACHING, ACADEMICS, BLOG, and a magnifying glass icon for SEARCH. Below the header, the main content area has a section titled "RECENT NEWS" followed by the title "ORCHESTRA IS THE DEFAULT BROADCAST MECHANISM IN APACHE SPARK". Underneath the title are three small icons: a clock (published date), a person (author), and a speech bubble (comments). The main text of the post discusses the recent release of Apache Spark and its promotion of the Orchestra broadcast mechanism. It also mentions the impact on MLlib. The entire content is framed by a white border.

RECENT NEWS

ORCHESTRA IS THE DEFAULT BROADCAST MECHANISM IN APACHE SPARK

⌚ SEPTEMBER 22, 2014 ⚑ MOSHARAF 💬 LEAVE A COMMENT

With its [recent release](#), Apache Spark has promoted Cornet—the BitTorrent-like broadcast mechanism proposed in [Orchestra](#) (SIGCOMM'11)—to become its default broadcast mechanism. It's great to see our research see the light of the real-world! Many thanks to Reynold and others for making it happen.

MLlib, the machine learning library of Spark, will [enjoy the biggest boost from this change](#) because of the broadcast-heavy nature of many machine learning algorithms.

Managing Data Transfers in Computer Clusters with Orchestra

Mosharaf Chowdhury, Matei Zaharia, Justin Ma, Michael I. Jordan, Ion Stoica
 University of California, Berkeley
 {mosharaf, matei, jtma, jordan, istoica}@cs.berkeley.edu

ABSTRACT

Cluster computing applications like MapReduce and Dryad transfer massive amounts of data between their computation stages. These transfers can have a significant impact on job performance, accounting for more than 50% of job completion times. Despite this impact, there has been relatively little work on optimizing the performance of these data transfers, with networking researchers traditionally focusing on per-flow traffic management. We address this limitation by proposing a global management architecture and a set of algorithms that (1) improve the transfer times of common communication patterns, such as broadcast and shuffle, and (2) allow scheduling policies at the transfer level, such as prioritizing a transfer over other transfers. Using a prototype implementation, we show that our solution improves broadcast completion times by up to $4.5\times$ compared to the status quo in Hadoop. We also show that transfer-level scheduling can reduce the completion time of high-priority transfers by $1.7\times$.

1 Introduction

The last decade has seen a rapid growth of cluster computing frameworks to analyze the increasing amounts of data collected and generated by web services like Google, Facebook and Yahoo!. These

clusters, operators aim to maximize the cluster utilization, while accommodating a variety of applications, workloads, and user requirements. To achieve these goals, several solutions have recently been proposed to reduce job completion times [11, 29, 43], accommodate interactive workloads [29, 43], and increase utilization [26, 29]. While in large part successful, these solutions have so far been focusing on scheduling and managing computation and storage resources, while mostly ignoring network resources.

However, managing and optimizing network activity is critical for improving job performance. Indeed, Hadoop traces from Facebook show that, on average, transferring data between successive stages accounts for 33% of the running times of jobs with reduce phases. Existing proposals for full bisection bandwidth networks [21, 23, 24, 35] along with flow-level scheduling [10, 21] can improve network performance, but they do not account for collective behaviors of flows due to the lack of job-level semantics.

In this paper, we argue that to maximize job performance, we need to optimize at the level of transfers, instead of individual flows. We define a *transfer* as the set of all flows transporting data between two stages of a job. In frameworks like MapReduce and Dryad, a stage cannot complete (or sometimes even start) before it receives all the data from the previous stage. Thus, the job running time depends on the time it takes to complete the *entire* transfer, rather than the duration of individual flows comprising it. To this end, we focus on two transfer patterns that occur in virtually all cluster computing frameworks and are responsible for most of the network traffic in these clusters: *shuffle* and *broadcast*. Shuffle captures the many-to-many communication pattern between the map and reduce stages in MapReduce, and between Dryad’s stages. Broadcast captures the one-to-many communication pattern employed by iterative optimization algorithms [45] as well as fragment-replicate joins in Hadoop [6].

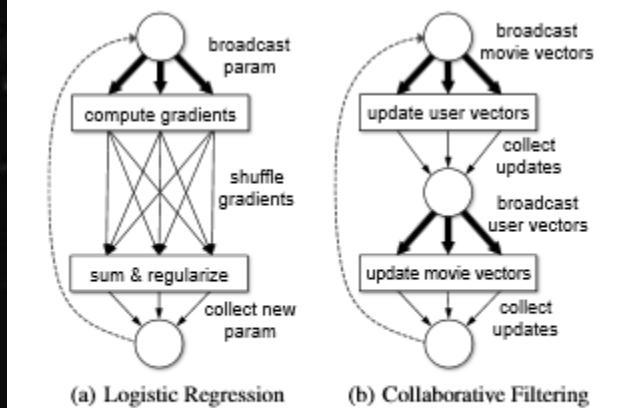

Figure 2: Per-iteration work flow diagrams for our motivating machine learning applications. The circle represents the master node and the boxes represent the set of worker nodes.

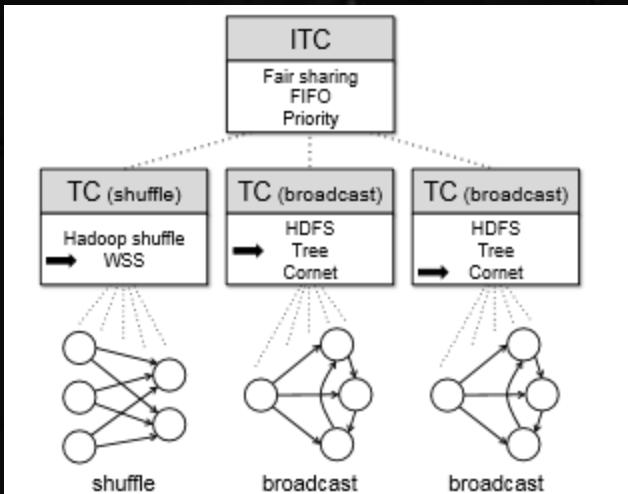

Figure 4: Orchestra architecture. An Inter-Transfer Controller (ITC) manages Transfer Controllers (TCs) for the active transfers. Each TC can choose among multiple transfer mechanisms depending on data size, number of nodes, and other factors. The ITC performs inter-transfer scheduling.

BITTORENT TECHNIQUE FOR BROADCAST

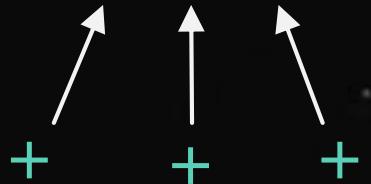

BITTORENT TECHNIQUE FOR BROADCAST

ACCUMULATORS

Accumulators are variables that can only be “added” to through an associative operation

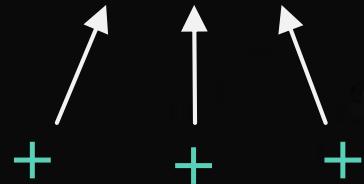

Used to implement counters and sums, efficiently in parallel

Spark natively supports accumulators of numeric value types and standard mutable collections, and programmers can extend for new types

Only the driver program can read an accumulator’s value, not the tasks

ACCUMULATORS

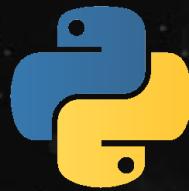

Scala:

```
val accum = sc.accumulator(0)  
  
sc.parallelize(Array(1, 2, 3, 4)).foreach(x => accum += x)  
  
accum.value
```

Python:

```
accum = sc.accumulator(0)  
rdd = sc.parallelize([1, 2, 3, 4])  
def f(x):  
    global accum  
    accum += x  
  
rdd.foreach(f)  
  
accum.value
```

PYSPARK ARCHITECTURE

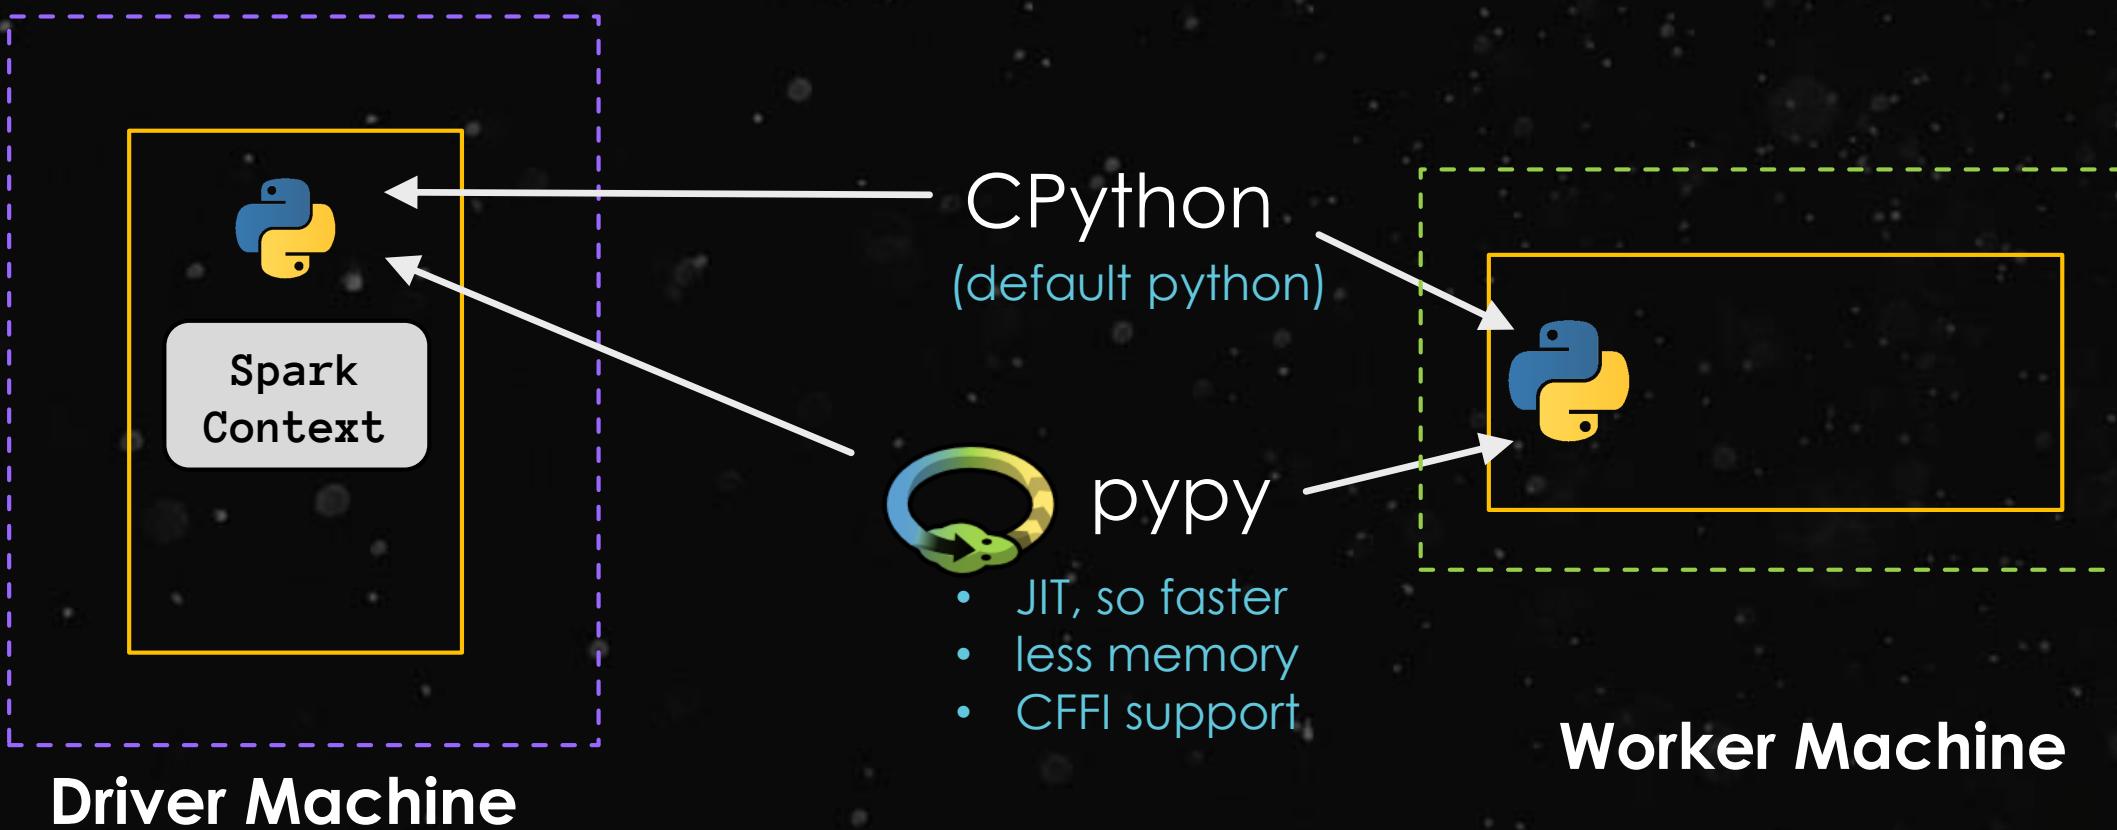

Data is stored as Pickled objects in an `RDD[Array[Byte]]`

`RDD[Array[` `,` `,` `,` `]]`

(100 KB – 1MB each picked object)

Choose Your Python Implementation

```
$ PYSPARK_DRIVER_PYTHON=pypy PYSPARK_PYTHON=pypy ./bin/pyspark
```

OR

```
$ PYSPARK_DRIVER_PYTHON=pypy PYSPARK_PYTHON=pypy ./bin/spark-submit wordcount.py
```

The performance speed up will depend on work load (from 20% to 3000%).

Here are some benchmarks:

Job	C P ython 2.7	Py P y 2.3.1	Speed up
Word Count	41 s	15 s	2.7 x
Sort	46 s	44 s	1.05 x
Stats	174 s	3.6 s	48 x

Here is the code used for benchmark:

```
rdd = sc.textFile("text")
def wordcount():
    rdd.flatMap(lambda x:x.split('/'))\
        .map(lambda x:(x,1)).reduceByKey(lambda x,y:x+y).collectAsMap()
def sort():
    rdd.sortBy(lambda x:x, 1).count()
def stats():
    sc.parallelize(range(1024), 20).flatMap(lambda x: xrange(5024)).stats()
```

spark.python.worker.memory	512m	Amount of memory to use per python worker process during aggregation, in the same format as JVM memory strings (e.g. 512m, 2g). If the memory used during aggregation goes above this amount, it will spill the data into disks.

Databricks demolishes big data benchmark to prove Spark is fast on disk, too

by Derrick Harris Oct. 10, 2014 - 1:49 PM PST

1 Comment

WHY SORTING?

- Stresses “shuffle” which underpins everything from SQL to Mllib
- Sorting is challenging b/c there is no reduction in data
- Sort 100 TB = 500 TB disk I/O and 200 TB network

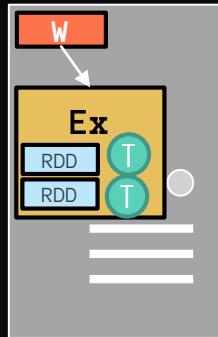

Engineering Investment in Spark:

- Sort-based shuffle (SPARK-2045)
- Netty native network transport (SPARK-2468)
- External shuffle service (SPARK-3796)

Clever Application level Techniques:

- GC and cache friendly memory layout
- Pipelining

TECHNIQUE USED FOR 100 TB SORT

EC2: i2.8xlarge

(206 workers)

- 32 slots per machine
- 6,592 slots total

- Intel Xeon CPU E5 2670 @ 2.5 GHz w/ 32 cores
- 244 GB of RAM
- 8 x 800 GB SSD and RAID 0 setup formatted with /ext4
- ~9.5 Gbps (1.1 GBps) bandwidth between 2 random nodes
 - Each record: 100 bytes (10 byte key & 90 byte value)
 - OpenJDK 1.7
 - HDFS 2.4.1 w/ short circuit local reads enabled
 - Apache Spark 1.2.0
 - Speculative Execution off
 - Increased Locality Wait to infinite
 - Compression turned off for input, output & network
 - Used Unsafe to put all the data off-heap and managed it manually (i.e. never triggered the GC)

=

groupByKey

sortByKey

reduceByKey

```
spark.shuffle.spill=false
```

(Affects reducer side and keeps all the data in memory)

EXTERNAL SHUFFLE SERVICE

- Worker JVM serves files

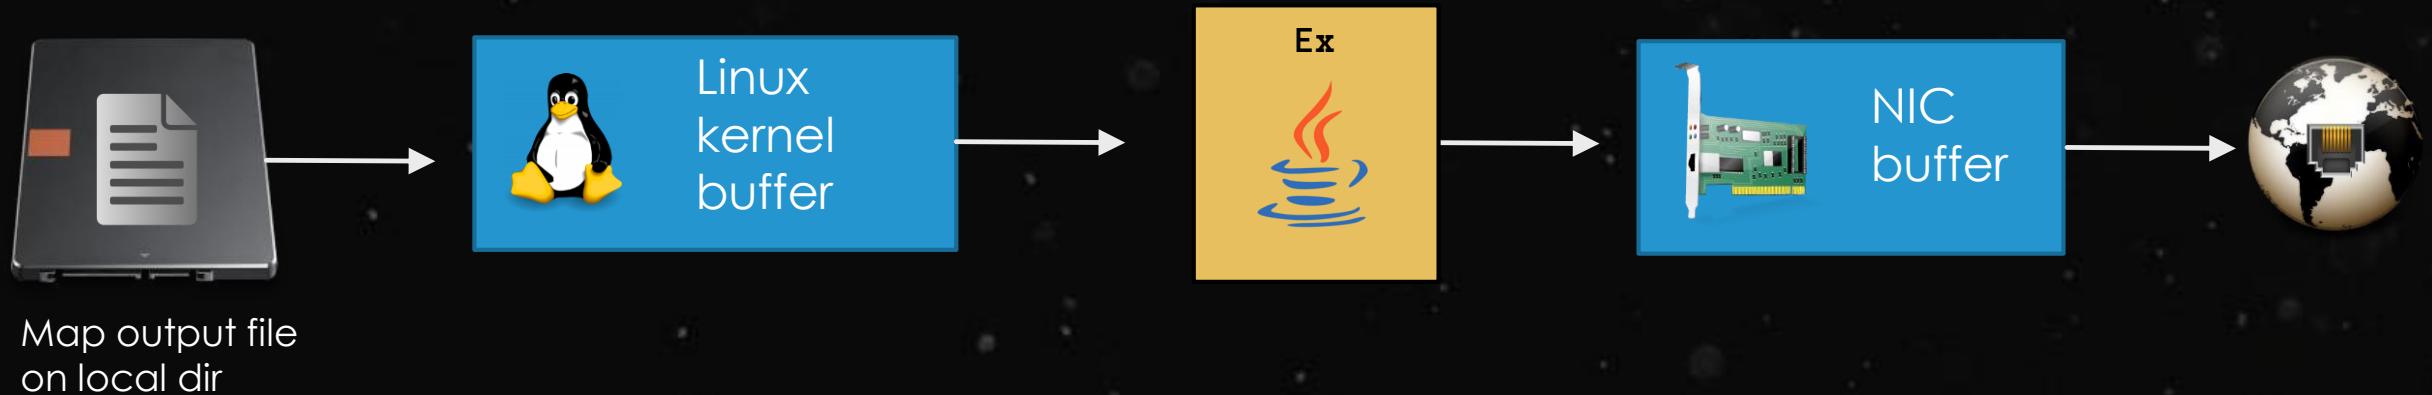

- Must turn this on for dynamic allocation in YARN
- Node Manager serves files

OLD TECHNIQUE FOR SERVING MAP OUTPUT FILES

- Was slow because it had to copy the data 3 times

NETTY NATIVE TRANSPORT

- Uses a technique called zero-copy
- Is a map-side optimization to serve data very quickly to requesting reducers

HASH BASED SHUFFLE

< 10,000 reducers

📄 = 5 blocks

- Notice that map has to keep 3 file handles open

- Entirely bounded by I/O reading from HDFS and writing out locally sorted files

- Mostly network bound

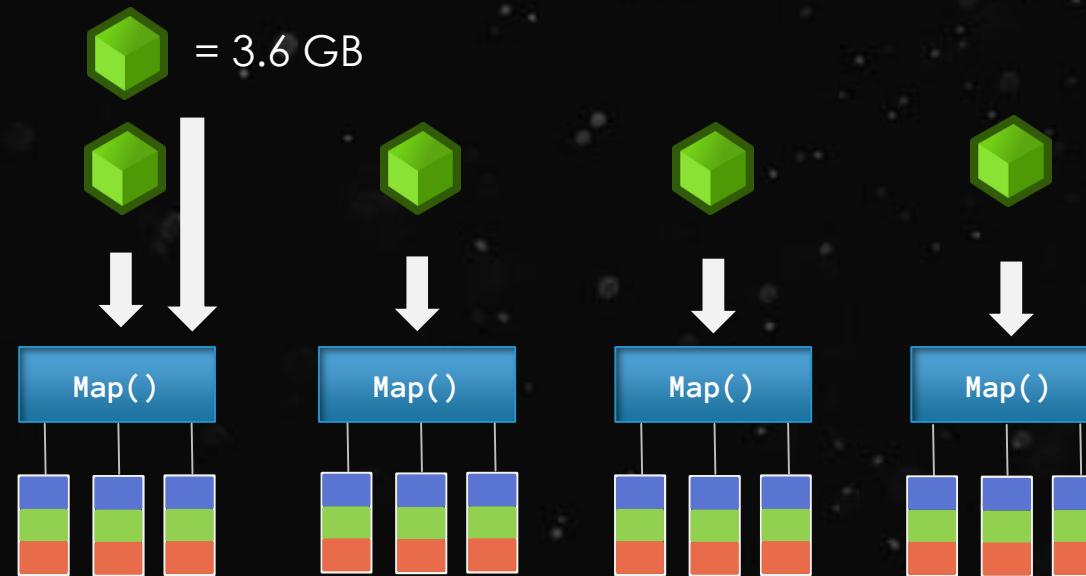

SORT BASED SHUFFLE

250,000+ reducers!

 **hadoop**
HDFS
(28,000 unique blocks)
RF = 2

= 3.6 GB

- Only one file handle open at a time

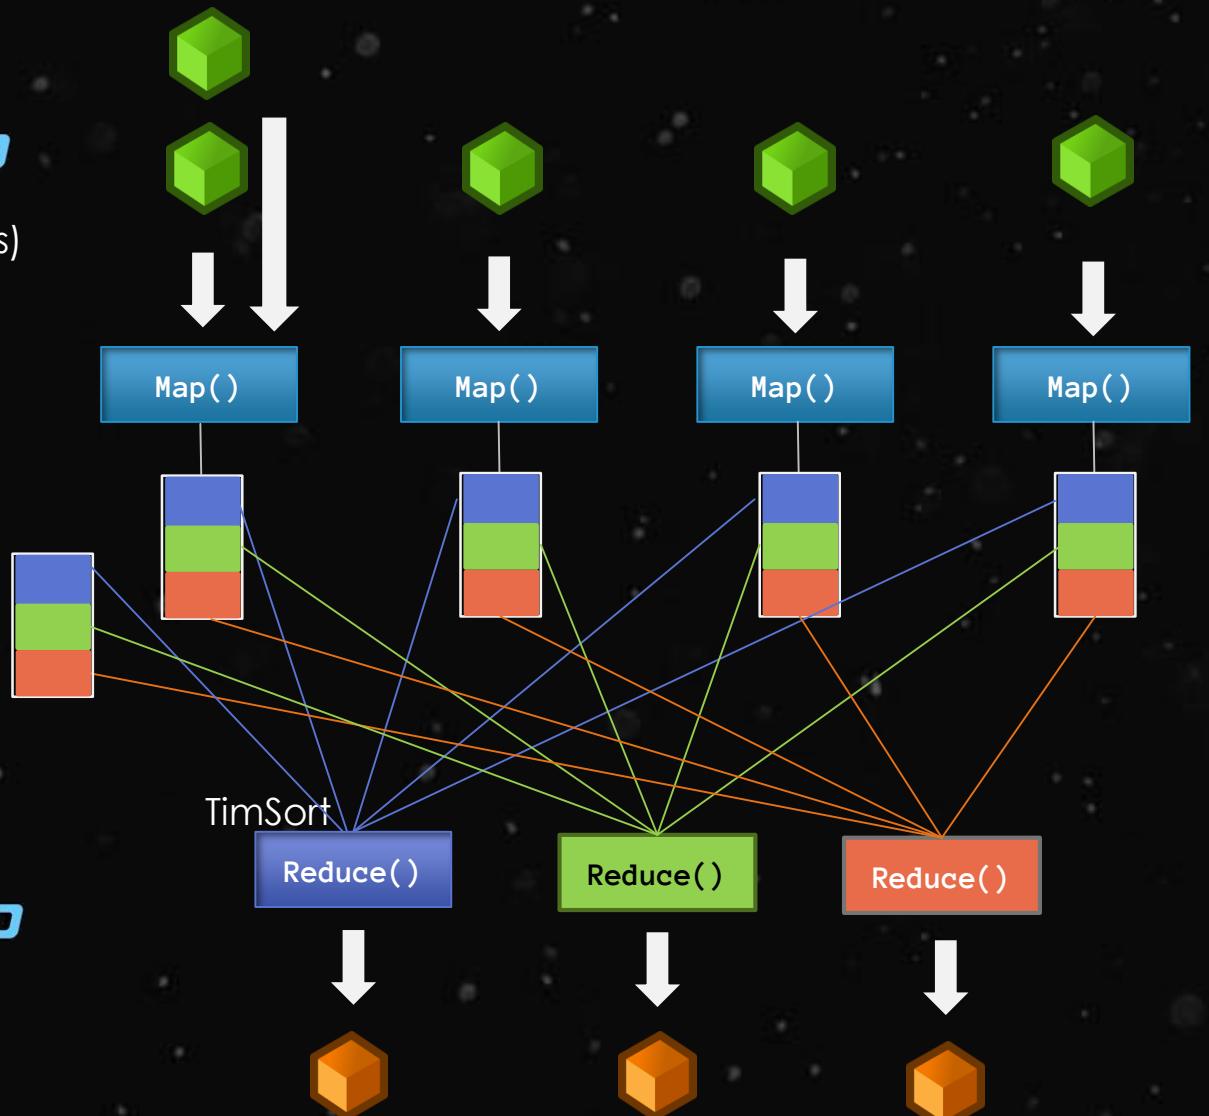

SORT BASED SHUFFLE

250,000+ reducers!

 **hadoop**
HDFS
(28,000 unique blocks)
RF = 2

MergeSort!

 **hadoop**
HDFS
RF = 2

NETWORK TRANSPORT

- Actual final run
- Fully saturated the 10 Gbit link

Sustaining 1.1GB/s/node during shuffle

SchemaRDD

- RDD of Row objects, each representing a record
- Row objects = type + col. name of each
- Stores data very efficiently by taking advantage of the schema
- SchemaRDDs are also regular RDDs, so you can run transformations like map() or filter()
- Allows new operations, like running SQL on objects

Introducing DataFrames in Spark for Large Scale Data Science

February 17, 2015 | by [Reynold Xin](#), [Michael Armbrust](#) and [Davies Liu](#)

[!\[\]\(fd4af61f5bab1e784a2cee3d23c76072_img.jpg\)](#) [!\[\]\(6bc51ec7ea9c66e2419d4041385965eb_img.jpg\)](#) [!\[\]\(55ad7467f2e3f840113b0022f98ad04d_img.jpg\)](#)

Today, we are excited to announce a new DataFrame API designed to make big data processing even easier for a wider audience.

When we first open sourced Spark, we aimed to provide a simple API for distributed data processing in general-purpose programming languages (Java, Python, Scala). Spark enabled distributed data processing through functional transformations on distributed collections of data (RDDs). This was an incredibly powerful API: tasks that used to take thousands of lines of code to express could be reduced to dozens.

INFERRING THE SCHEMA USING REFLECTION

Warning!

Only looks at first row

```
# sc is an existing SparkContext.  
from pyspark.sql import SQLContext, Row  
sqlContext = SQLContext(sc)  
  
# Load a text file and convert each line to a Row.  
lines = sc.textFile("examples/src/main/resources/people.txt")  
parts = lines.map(lambda l: l.split(",")).  
people = parts.map(lambda p: Row(name=p[0], age=int(p[1])))  
  
# Infer the schema, and register the SchemaRDD as a table.  
schemaPeople = sqlContext.inferSchema(people)  
schemaPeople.registerTempTable("people")  
  
# SQL can be run over SchemaRDDs that have been registered as a table.  
teenagers = sqlContext.sql("SELECT name FROM people WHERE age >= 13 AND age <= 19")  
  
# The results of SQL queries are RDDs and support all the normal RDD operations.  
teenNames = teenagers.map(lambda p: "Name: " + p.name)  
for teenName in teenNames.collect():  
    print teenName
```

PROGRAMMATICALLY SPECIFYING THE SCHEMA

```
# Import SQLContext and data types
from pyspark.sql import *

# sc is an existing SparkContext.
sqlContext = SQLContext(sc)

# Load a text file and convert each line to a tuple.
lines = sc.textFile("examples/src/main/resources/people.txt")
parts = lines.map(lambda l: l.split(","))
people = parts.map(lambda p: (p[0], p[1].strip()))

# The schema is encoded in a string.
schemaString = "name age"

fields = [StructField(field_name, StringType(), True) for field_name in schemaString.split()]
schema = StructType(fields)

# Apply the schema to the RDD.
schemaPeople = sqlContext.applySchema(people, schema)

# Register the SchemaRDD as a table.
schemaPeople.registerTempTable("people")

# SQL can be run over SchemaRDDs that have been registered as a table.
results = sqlContext.sql("SELECT name FROM people")

# The results of SQL queries are RDDs and support all the normal RDD operations.
names = results.map(lambda p: "Name: " + p.name)
for name in names.collect():
    print name
```

```
# sqlContext from the previous example is used in this example.

schemaPeople # The SchemaRDD from the previous example.

# SchemaRDDs can be saved as Parquet files, maintaining the schema information.
schemaPeople.saveAsParquetFile("people.parquet")

# Read in the Parquet file created above. Parquet files are self-describing so the schema is preserved.
# The result of loading a parquet file is also a SchemaRDD.
parquetFile = sqlContext.parquetFile("people.parquet")

# Parquet files can also be registered as tables and then used in SQL statements.
parquetFile.registerTempTable("parquetFile");
teenagers = sqlContext.sql("SELECT name FROM parquetFile WHERE age >= 13 AND age <= 19")
teenNames = teenagers.map(lambda p: "Name: " + p.name)
for teenName in teenNames.collect():
    print teenName
```

Configuration of Parquet can be done using the `setconf` method on `SQLContext` or by running `SET key=value` commands using SQL.

Property Name	Default	Meaning
<code>spark.sql.parquet.binaryAsString</code>	false	Some other Parquet-producing systems, in particular Impala and older versions of Spark SQL, do not differentiate between binary data and strings when writing out the Parquet schema. This flag tells Spark SQL to interpret binary data as a string to provide compatibility with these systems.
<code>spark.sql.parquet.cacheMetadata</code>	true	Turns on caching of Parquet schema metadata. Can speed up querying of static data.
<code>spark.sql.parquet.compression.codec</code>	gzip	Sets the compression codec use when writing Parquet files. Acceptable values include: uncompressed, snappy, gzip, lzo.
<code>spark.sql.parquet.filterPushdown</code>	false	Turn on Parquet filter pushdown optimization. This feature is turned off by default because of a known bug in Parquet 1.6.0rc3 (PARQUET-136). However, if your table doesn't contain any nullable string or binary columns, it's still safe to turn this feature on.
<code>spark.sql.hive.convertMetastoreParquet</code>	true	When set to false, Spark SQL will use the Hive SerDe for parquet tables instead of the built in support.

org.apache.spark.sql SchemaRDD

class **SchemaRDD** extends [RDD\[Row\]](#) with SchemaRDDLike

An RDD of [Row](#) objects that has an associated schema. In addition to standard RDD functions, SchemaRDDs can be used in relational queries, as shown in the examples below. [Alpha Component](#)

Importing a [SQLContext](#) brings an implicit into scope that automatically converts a standard RDD whose elements are scala case classes into a SchemaRDD. This conversion can also be done explicitly using the [createSchemaRDD](#) function on a [SQLContext](#).

A SchemaRDD can also be created by loading data in from external sources. Examples are loading data from Parquet files by using the [parquetFile](#) method on [SQLContext](#) and loading JSON datasets by using [jsonFile](#) and [jsonRDD](#) methods on [SQLContext](#).

SQL Queries

A SchemaRDD can be registered as a table in the [SQLContext](#) that was used to create it. Once an RDD has been registered as a table, it can be used in the FROM clause of SQL statements.

```
// One method for defining the schema of an RDD is to make a case class with the desired column
// names and types.
case class Record(key: Int, value: String)

val sc: SparkContext // An existing spark context.
val sqlContext = new SQLContext(sc)

// Importing the SQL context gives access to all the SQL functions and implicit conversions.
import sqlContext._

val rdd = sc.parallelize((1 to 100).map(i => Record(i, s"val_$i")))
// Any RDD containing case classes can be registered as a table. The schema of the table is
// automatically inferred using scala reflection.
rdd.registerTempTable("records")

val results: SchemaRDD = sql("SELECT * FROM records")
```

Spark Streaming + Flume Integration Guide

Apache Flume is a distributed, reliable, and available service for efficiently collecting, aggregating, and moving large amounts of log data. Here we explain how to configure Flume and Spark Streaming to receive data from Flume. There are two approaches to this.

Approach 1: Flume-style Push-based Approach

Flume is designed to push data between Flume agents. In this approach, Spark Streaming essentially sets up a receiver that acts an Avro agent for Flume, to which Flume can push the data. Here are the configuration steps.

General Requirements

Choose a machine in your cluster such that

- When your Flume + Spark Streaming application is launched, one of the Spark workers must run on that machine.
- Flume can be configured to push data to a port on that machine.

Due to the push model, the streaming application needs to be up, with the receiver scheduled and listening on the chosen port, for Flume to be able push data.

Configuring Flume

Configure Flume agent to send data to an Avro sink by having the following in the configuration file.

```
agent.sinks = avrosink
```

Spark Streaming + Kafka Integration Guide

Apache Kafka is publish-subscribe messaging rethought as a distributed, partitioned, replicated commit log service. Here we explain how to configure Spark Streaming to receive data from Kafka.

- Linking:** In your SBT/Maven project definition, link your streaming application against the following artifact (see [Linking section](#) in the main programming guide for further information).

```
groupId = org.apache.spark  
artifactId = spark-streaming-kafka_2.10  
version = 1.2.0
```

- Programming:** In the streaming application code, import kafkautils and create input DStream as follows.

Scala Java

```
import org.apache.spark.streaming.kafka._  
  
val kafkastream = KafkaUtils.createStream(  
    ...
```

TRANSFORMATIONS ON DSTREAMS

map($f(x)$)

reduce($f(x)$)

union($otherStream$)

updateStateByKey($f(x)$)^{*}

flatMap($f(x)$)

join($otherStream$, [numTasks])

filter($f(x)$)

cogroup($otherStream$, [numTasks])

repartition($numPartitions$)

RDD

transform($f(x)$)

RDD

count()

reduceByKey($f(x)$, [numTasks])

countByValue()

TRANSFORMATIONS ON DSTREAMS

updateStateByKey(*f(x)*)^{*}

: allows you to maintain arbitrary state while continuously updating it with new information.

To use:

1) Define the state

(an arbitrary data type)

2) Define the state update function

(specify with a function how to update the state using the previous state and new values from the input stream)

```
pairs = (word, 1)  
(cat, 1)
```

To maintain a running count of each word seen in a text data stream (*here running count is an integer type of state*):

```
def updateFunction(newValues, runningCount):  
    if runningCount is None:  
        runningCount = 0  
    return sum(newValues, runningCount) # add the  
        # new values with the previous running count  
        # to get the new count
```

```
runningCounts = pairs.updateStateByKey(updateFunction)
```

* Requires a checkpoint directory to be configured

TRANSFORMATIONS ON DSTREAMS

```
RDD  
↓  
transform( f(x) ) : can be used to apply any RDD operation that  
is not exposed in the DStream API.  
↓  
RDD
```

For example:

- Functionality to join every batch in a data stream with another dataset is not directly exposed in the DStream API.
- If you want to do real-time data cleaning by joining the input data stream with pre-computed spam information and then filtering based on it.

```
spamInfoRDD = sc.pickleFile(...) # RDD containing spam information  
# join data stream with spam information to do data cleaning  
cleanedDStream = wordCounts.transform(lambda rdd:  
    rdd.join(spamInfoRDD).filter(...))
```

Window Length: * 3 time units

Sliding Interval: * 2 time units

* Both of these must be multiples of the batch interval of the source DStream

WINDOW OPERATIONS

Original
DStream

Windowed
DStream

Reduce last 30 seconds of data, every 10 seconds

```
windowedWordCounts = pairs.reduceByKeyAndWindow(lambda x, y: x + y, lambda x, y: x - y, 30, 10)
```

COMMON WINDOW OPERATIONS

`window(windowLength, slideInterval)`

`countByValueAndWindow(windowLength, slideInterval, [numTasks])`

`countByWindow(windowLength, slideInterval)`

`reduceByWindow(f(x), windowLength, slideInterval)`

`reduceByKeyAndWindow(f(x), windowLength, slideInterval, [numTasks])`

`reduceByKeyAndWindow(f(x), V(x), windowLength, slideInterval, [numTasks])`
